† Bouillaud, as M. Broca handsomely admitted, had also recognised the special relation of the left side of the brain to spoken language. "N'est-ce pas que nous écrivons, nous dessinons, etc., de la main droite? . . . eh bien, serait-il absolument impossible, que pour certains actes aux quels sont affectés les hémisphères cérébraux, la parole par exemple, nous fussions pour ainsi dire gauchers?" (Discours à l'Acad. imp. de Médecine, 1865.)

to be set in action simultaneously. It may be noted, as one inference from Dr Broadbent's hypothesis, that if hemiplegia and aphasia occur together, the lesion must be one which either involves simultaneously Broca's convolutions and the corpus striatum, or else affects an extensive area of the left hemisphere in the neighbourhood of the fissure of Rolando. Whichever is the case, the cause of the disease must almost always be obstruction of the Sylvian artery, whether by embolism, thrombosis, or syphilis.

If in a given case plugging of the Sylvian artery should be overlooked—and until lately it was not usual for pathologists to devote special attention to the condition of the cerebral vessels—it might easily be supposed that the only disease was in the corpus striatum, and that this had caused the aphasia. In July, 1877, the author made an autopsy in which it would have been quite possible to commit this mistake; the patient was aphasic, and the only obvious lesion of the brain was in the corpus striatum; but the Sylvian artery contained an embolism at its very commencement.

In the second place, aphasia cannot be caused by a lesion of any part of the surface, even of the left hemisphere, with the exception of Broca's region. Perhaps this position is not so completely established, because cases are very rare in which a morbid change is limited to a single spot on the convexity of the brain with sufficient accuracy to throw any light upon the question. A woman at Guy's Hospital suffering from cancer of the breast had transitory attacks of aphasia: it was conjectured that she had a secondary nodule in the third frontal convolution of the left hemisphere of her brain; and this diagnosis was afterwards verified by an autopsy. As Dr Broadbent observed in 1872, it is remarkable how large a proportion of apparently exceptional cases break down under careful scrutiny.

It has been asserted—but more on theoretical grounds than by convincing anatomical evidence—that the centre for sensory aphasia, or word-deafness, is in the superior temporo-sphenoidal convolution, and that for agraphia, or word-blindness in the angular gyrus.

Theory of aphasia.—Reverting now to the physiological causation of aphasia, we have to ask how it can be that loss of speech is always dependent on a lesion of the surface of the left hemisphere—except in left-handed persons, in whom, as we have seen, the disease is in the corresponding part of the right hemisphere. Dr Moxon first threw light upon this curious fact, and suggested an explanation which has virtually been accepted by subsequent writers. His view ('Med.-Chir. Rev.,' 1866) is that the two halves of the brain are originally symmetrical, and resemble one another in their functional capacities, but that in the course of education one side only becomes stored with those ideas of associated movements which are required for the performance of bilateral actions, such as are concerned in speech; or, as he elsewhere puts it, one side of the tongue *guides* the other; just as the right hand guides the left one when they are made to execute similar motions, it being notorious that this requires infinitely less attention than the execution of opposed motions by the two hands at once. Dr Moxon does not more fully explain why the process of education should take place on one side of the brain rather than the other; and this has been regarded as a difficulty by some later writers; but, as we have seen, the associated movements which make up the act of writing, and in which only one hand is concerned, are so closely connected with those that constitute speech, that agraphia very commonly accompanies aphasia. Now, it is true that all men do not learn to write; but there is perhaps no savage who does

not, from his earliest infancy, become accustomed to employ one hand rather than the other in the gestures by which he supplements speech; and it was a suggestion made by Broca himself that this preference of the left hemisphere for so many other purposes led to the education of convolutions of that hemisphere for the "motor processes" concerned in speech.

Theory of amnesia.—We have still to ask what are the relations of aphasia to "incoming" language—that part of the faculty of speech which consists in the recognition of words spoken by others. Many modern writers, following Dr Sanders and Dr William Ogle, admit a separate variety of aphasia, which they term *amnesic* or *amnemonic*. The characteristic symptom of it is, they say, that the patient is able to utter words, provided that he has first heard them spoken by another person. In fact, one may be able by prompting to make him speak pretty freely, although he may be incapable of saying anything in reply to a question which does not suggest its own answer. Now, it is, in the first place, to be observed that the value of this test is limited to those cases in which it yields a positive result. If the man continues altogether speechless, after one has repeated again and again the word or the sentence which he is asked to utter, one gains nothing by the experiment. That the memory for "incoming" language is not altogether lost may, indeed, sometimes be obvious from the gestures of intelligence which such a person makes if the right word is suggested to him, and from his strongly marked dissent when other words are substituted for it. Moreover, in those cases in which an attack of aphasia rapidly passes off, the patient may be able to give a complete account of all that occurred during his illness, and to state that his power of thinking was altogether unaffected. Prof. Lordat, for example, who once suffered in this way, said that he was able to combine abstract ideas, and to distinguish them accurately. Being accustomed to teach, he thought over the subject-matter of a lecture, and found that he could dispose in his mind the chief points without difficulty, and introduce any changes that he pleased in their order. He thought of the Doxology, but he was not able to recollect a single word of it. We must leave it to the metaphysicians to discuss how far it is possible for the mental processes to be carried on without the revival of words as symbols in the consciousness; but it is clear that in M. Lordat's case the fault lay in the machinery of expression alone—always supposing that he was able to recall past states of consciousness with complete accuracy.

Again, when aphasia is incomplete, so that the patient can utter one or two words, and uses them in answer to every question that may be put to him, he is often perfectly conscious of the mistakes that he commits. Every physician has seen such cases, and will remember the shake of the head, the puzzled look, the smile—half amusement, half vexation—the repeated attempts to find the right word, and the beam of satisfaction if by chance it at last comes off the tongue.

These facts seem to prove beyond dispute that the memory of language may be unimpaired, even when there is complete aphasia.

Mental condition in aphasia.—Let us now look at another side of the question. Many patients affected with partial aphasia go on uttering the same word for months or years, without seeming to know that anything is amiss with them. Trousseau studied very carefully the case of an artist who, according to his own account, suffered from nothing but failure of speech, being able to understand perfectly all that he read, and being in full possession of his intellect. It turned out that he made the grossest

mistakes in reading aloud, that he wrote one word for another without being aware of it, and that when asked to sketch a human figure he drew like a child who had never been taught. The same writer, referring to another case, lays stress on the fact that the patient, who read the newspaper, and expressed by signs that he understood it perfectly, was nevertheless in the habit of reading the sheet over and over again in the same day. And a girl under his care had for a whole year one book in her hands, and almost always read the same page. He suggests that a very good test of the understanding of an aphasic patient is to take up a book, and to read a few lines, telling the patient to follow with his eyes, and to turn over at the proper moment. The artist, whose case has already been referred to, could never do this correctly. From these observations Trousseau concludes, in spite of the facts mentioned in the previous paragraph, that in aphasia there is not merely loss of speech, but also impairment of intelligence. The lesions which cause aphasia are in most cases such as interfere with the supply of blood to a large part of one hemisphere, and therefore they often produce mental symptoms independent of loss of speech.

That other symptoms have no connection with the aphasia is proved by the fact that there is often *anosmia* in the corresponding nostril. In the 'Med.-Chir. Transactions' for 1870, Dr William Ogle refers to seven instances of this: he supposes that the so-called external root of the olfactory bulb becomes implicated when it is passing to the floor of the fissure of Sylvius.

The question is—not what defect of understanding *may* be found in aphasic patients, but what amount of intelligence they ever retain. Instances of pure aphasia, unattended with paralysis of the limbs, are especially worthy of study in reference to this question. In such cases, while the loss of speech is often absolute, the intellect may be unimpaired.*

But they are the exceptions; for one sees patients with right hemiplegia who go on for years, unable to utter a single word, or to communicate in any way with their friends. It would be sad to suppose that such persons are really in possession of all their mental faculties, and that they are living, as it were, imprisoned within an iron mask. Happily this is as unlikely as it would be melancholy, for these patients show often by their gestures that they are not miserable, and often they are obviously impaired in intellect. Moreover, those who suffer from left hemiplegia, dependent upon any extensive lesion of the right hemisphere, manifest an equally marked deficiency of intelligence, although they are not deprived of speech.

These considerations lead to the conclusion that, although loss of speech is often associated with inability to understand "incoming" language or recognise mistakes made in "outgoing" language, yet the two things are essentially independent of one another, and that aphasia associated with

* The following is a striking instance:—"About three in the morning, as near as I can guess, I woke and sat up; when I felt a confusion and indistinctness in my head, which lasted, I suppose, about half a minute. I was alarmed, and prayed God that, however He might afflict my body, He would spare my understanding. This prayer, that I might try the integrity of my faculties, I made in Latin verse. The lines were not very good, but I knew them not to be very good. I made them easily and concluded myself to be unimpaired in my faculties. Soon after I perceived that I had suffered a paralytic stroke, and that my speech was taken from me. I had no pain. . . . . I then wrote to Dr Taylor to come to me and bring Dr Heberden. . . . . In penning this note I had some difficulty; my hand, I know not how or why, made wrong letters" (Dr Johnson to Mrs Thrale, June 17th, 1783, *anno ætatis* 74). He recovered quickly in a few days from this attack of aphasia with agraphia, but without motor paralysis; and the cerebral hæmorrhage (for such no doubt it was) did not return.

amnesia indicates the existence of a lesion extending beyond the limits of Broca's region.

Dr Broadbent arrived at nearly the same conclusion (cf. 'Med.-Chir. Trans.,' 1872, p. 174). He maintains the truth of Broca's theory, so far as concerns the seat of the lesions which are attended with aphasia when it occurs independently of any failure of intelligence. This theory, however, is very far from implying that the whole of the faculty of language is localised in any one part of the hemispheres; it only asserts that a certain spot in the left hemisphere contains machinery, without the use of which a person cannot utter words, nor convey his thoughts to the pen in writing.

Recovery from aphasia.—It is remarkable that, although a patient, after a paralytic stroke, regains his power of speech, if it has been lost by "the shock," soon after consciousness is restored, and although he regains the articulation which has been damaged by partial paralysis of the tongue and lips before the power in his leg, and usually long before that in his arm—yet when a patient with right hemiplegia is also aphasic (in the strict sense of the word) his recovery of speech comes, as a rule, latest of all, or at least when there only remains slight awkwardness in the fingers or an almost imperceptible halt in the gait.

There is reason to believe that when Broca's region has been destroyed, the power of speech may still be recovered, not by regeneration of the lost tissue, but by the corresponding part of the right hemisphere taking on the action of the left; just as a draughtsman after losing his right hand would, in learning to draw with his left, be educating not only his muscles and nerves, but also the motor centres of his right hemisphere.

The writer had several years ago under his care in Stephen Ward a young man who was admitted with complete aphasia and right hemiplegia, probably the result of syphilitic stenosis of his left Sylvian artery. While slowly regaining power of movement and improving in health, the sister of the ward tried to teach him to speak, and found the only way was to begin from the beginning by naming objects (and printed words—so as to teach him to read again also), and making him imitate the sounds over and over again. The result was a good degree of success. In the same way the monophrasic woman mentioned before, who said *ten-ten*, was taught by two successive clinical clerks to print letters with her left hand, and to recognise printed letters. Here the success was but slight, perhaps owing to the greater age of the scholar or the smaller patience of the teachers.

Aphasia in lunatics.—There is still one point of view from which it is necessary to consider the pathology of aphasia; namely, as to whether this symptom, when occurring in persons of unsound mind, is necessarily dependent upon a lesion in Broca's region. Dr Bastian mentions the case of a lunatic who did not utter a single word for several years, except during two brief intervals, once when he had an attack of pleurisy that lasted some days, and once when he was suffering from toothache. The late Dr Forbes Winslow relates a similar instance; a person who had been insane for fifty-two years did not speak during thirty years, but recovered speech and answered questions perfectly well during the last fifteen years of his life. In such cases there is surely no reason to suppose that there was any local lesion in the brain.

The same observation may be made in reference to some of the cases which Trousseau gives as examples of aphasia; for instance, that of the lady who was wont to welcome her visitors by exclaiming *pig*, *animal*, *fool*, without

understanding the meaning of the expressions she used. It is also applicable to an example of supposed agraphia, in a lunatic at Broadmoor, which has been recorded by Dr Bastian; here the inability to write was of an amnesic type, and may be regarded as one of the symptoms of insanity ('The Brain as an Organ of Mind,' 3rd ed., p. 660).

APOPLEXY.*—This term originally signified a "stroke" (see note), by which the patient falls "like an ox struck down by the butcher;" and we shall here use it in this its proper sense. But the word apoplexy was transferred by metonymy to effusion of blood upon the brain, which was found to be the most common cause of such attacks when autopsies began to be made; and this use of the word was afterwards extended to hæmorrhages in other parts, so that pulmonary apoplexy, retinal apoplexy, and apoplexy of the suprarenal capsules are spoken of. There is, however, no advantage in employing apoplexy as a mere synonym for cerebral hæmorrhage; and in clinical medicine it is desirable to have a name for that form of coma which is due to disturbance of the cerebral circulation from some local cause acting within the cranial cavity—usually but not always rupture of an artery—as distinguished from failure of the heart's action on the one hand, and, on the other, from narcotic or alcoholic poisoning, uræmia, epilepsy, or external injury. For this purpose the word apoplexy appears to be suitable, and it has been so applied by a long chain of authorities, including some of the most distinguished names in medical literature.

Symptoms.—A patient in an apoplectic fit lies "deprived of sense and motion." He cannot be roused, but there may be varying degrees of insensibility. Sometimes the well-known voice of a wife or son may elicit an unintelligible muttering or growling sound in reply, or the application of a spoon to the lips may cause them to be closed in automatic refusal of food; or one hand may be used to rub or scratch the side of the face or body. More often there are no such indications of even partial consciousness; the limbs remain in whatever position they happen to fall; the respiratory movements and the beating of the heart alone indicate life.

The pupils are generally torpid, and often insensible to light; they are sometimes equal and of normal size, sometimes both dilated or both minutely contracted, sometimes unequal. The conjunctivæ can often be touched without exciting reflex movement in the eyelids. The cutaneous reflexes are diminished or abolished, rarely increased. Pinching or pricking the skin seldom leads to any manifestation of consciousness. Sometimes, however, the hand or the foot is drawn away on one side and not on the other, or it may be found that when the arms are lifted and allowed to drop upon the bed, one is a dead weight; or the arm and the leg on one side may be rigid, on the opposite side relaxed. Such indications of hemiplegia are important, as is also the conjugate deviation of the eyes described above (p. 563).

The appearance of the countenance varies greatly in different cases; sometimes it is pale, sometimes congested and purple, with lividity of the lips and tongue; the features are often turgid and swollen, and the forehead and cheeks bathed in perspiration, which saturates the linen and stands in large drops upon the face.

The *temperature*, as measured by the thermometer, has been carefully

* *Gr.* Ἀποπληγία, ἀποπληξία, a stroke, a classical Greek word from ἀποπλήσσω, to strike, to disable (Soph., 'Antigone,' v, 1189, where it is applied to syncope). Used by Hippocrates of a "stroke" of the palsy, but applied to one limb, as σκέλος ἀποπληκτικόν, a paralysed leg.—*Lat.* Sideratio.—*Fr.* Coup de sang.—*Germ.* Schlagfluss.

investigated by Bourneville. He finds that there is at first a slight fall, amounting to about 2° Fahrenheit. In rapidly fatal cases this continues until death; but if life is prolonged the temperature rises, and for several days it may remain at about 100°. When death occurs at an interval of more than ten hours from the commencement of the attack it may be preceded by a rapid elevation of temperature. This was noticed by Dr Hughlings Jackson, and, as he observes, is a very unfavourable sign. In one fatal case at Guy's Hospital the thermometer registered 107°. When recovery is to take place, the temperature, if it has risen, commonly returns to the normal point two or three days after the commencement of the attack.

The *pulse* may be either increased or diminished in frequency; the prognosis is bad if it is greatly above or greatly below the average—say below 60 or above 120. Unfortunately, the converse is not always true; for example, Dr Jackson mentions a case in which the pulse was 72 within five hours of the death of the patient. As a rule the pulse becomes more rapid as the case goes on towards a fatal termination; but the worst sign of all is irregularity of the pulsations of the heart, a succession of rapid beats being followed by a series of beats at long intervals. Formerly great stress was laid upon the "full" and "labouring" character of the radial pulse in apoplexy, and it was supposed to be a proof of the necessity for venæsection. We now refer this character either to want of elasticity from atheroma of the aorta, or to the high arterial tension of chronic Bright's disease.

The *breathing* is sometimes infrequent; there may be as few as three or four respirations in the minute. Towards the last it often happens that the patient ceases to breathe for perhaps a minute, and a purple flush diffuses itself over the countenance, but afterwards a deep breath is again drawn, the face resumes its natural colour, and the respiration goes on as before. This may be repeated several times, until at length a final pause occurs; the heart may then go on beating for a considerable time, but at length its pulsations cease and the patient is dead. In some cases the respiration assumes the characters observed by Cheyne and Stokes, and known by their names.

In many cases apoplexy destroys life by a more gradual increase of obstruction to the breathing, which seems to depend upon a concurrence of several distinct causes. One of these is the supervention of inflammatory œdema, beginning in the bases of the lungs and spreading upwards through the back parts of those organs. Another is the accumulation of a thin secretion in the air-passages, which becomes beaten up into a froth by the inhaled air, and may completely fill the main bronchi and even the trachea. It is probable that the pouring out of this fluid is often partly caused by the entrance of fluid nourishment; for when a patient is comatose, milk and beef-tea and brandy are very apt to run down into the larynx without giving rise to any warning cough or sensation of choking; but no doubt another important cause is the impediment to the act of respiration which is due to paralysis of the tongue and fauces. Everyone who has made many examinations on the bodies of those who have been suffocated knows how large a quantity of frothy fluid is found in the air-passages, even when death has been rapid; but an apoplectic patient may lie for days in a condition in which there is much interference with the breathing. This is shown not only by the lividity of his countenance, but also by the fact that the entrance and exit of air are accompanied by a noise which is commonly called *stertor*. The causes that lead to the occurrence of this sound were clearly pointed out by Dr Bowles, of Folkestone, in the 'Med.-Chir. Trans.' for 1860. He

admits that when the mouth is partially open the soft palate sometimes drops upon the tongue, and vibrates as the air rushes in beneath it; but he ascribes far more importance to a change in the position of the tongue itself; he shows that when the mouth falls open, the point of attachment of the lingual muscles to the symphysis is carried backwards, and he thinks that the tongue then comes into contact with the posterior wall of the pharynx. As might be expected, this is especially apt to occur while the patient lies supine. Dr Bowles finds that turning him over on his side, with the mouth inclined so that the saliva and mucus can drain away, often causes the entire disappearance of stertor, and may be followed by a decided improvement in some of the other symptoms.

When the breathing is noisy the cheek is often puffed out at each expiration in consequence of paralysis of the buccinator muscle; this symptom suggests an unfavourable prognosis.

Duration.—The period that an apoplectic seizure lasts is very variable. In some exceedingly rare instances death takes place a few minutes after the commencement of the cerebral symptoms. Thus Dr Jackson mentions the case of a woman who was sitting at the tea-table, when she stopped in the middle of a laugh, cried out, "Oh, my head!" fell back in her chair, and died within not more than *five minutes*. Abercrombie relates a similar occurrence in a woman who was one evening attending a crowded meeting, and who seemed to be in perfect health. Towards the conclusion she uttered a loud scream, and fell down insensible. She was immediately carried out, remained pale and unconscious, and within *five minutes* she was dead. In both these cases meningeal hæmorrhage was found.

In 1864 there was brought to Guy's Hospital the body of a woman who had died *almost instantaneously* as she was returning home from the theatre with her children; in that instance also a large quantity of blood had been poured out over the sides and base of the brain. The author once found at an autopsy a large clot in the left hemisphere, bursting into the lateral ventricle. The patient, a man, aged forty-one, was in a surgical ward for some laryngeal affection, and had been sent down to the dispensary to fetch the medicines; on his way he had a fit, became comatose, and died within *ten minutes*.

One would have expected that hæmorrhage into the pons would often cause instantaneous death. But Dr Jackson remarks that he has never seen such a case, although he has known a woman lie deeply comatose for some hours, in whom this part of the brain was hollowed out into a mere shell. In the most rapidly fatal case of a clot in the pons recorded at Guy's Hospital death occurred in *forty minutes;* two patients lived each for two hours, one nine hours and a half, one thirteen hours, one sixteen hours, and one *two days*.*

Meningeal hæmorrhage commonly proves fatal within forty-eight hours. But in the ordinary form of apoplexy, in which blood is effused into the neighbourhood of the corpus striatum, life is often maintained for a much longer period. In twelve cases at Guy's Hospital death did not occur until between the second and the seventh days; and in six cases at the end of ten, twelve, thirteen, sixteen, nineteen, and again nineteen days respectively. It is worthy of remark that two among these six cases were examples of a very rare occurrence, the formation of a clot within the substance of the brain, which was large enough to destroy life, but which yet failed to reach either

* Of seventy-eight cases of hæmorrhage into the pons collected by Bode and quoted by Ross, forty-six proved fatal within twenty-four hours.

the lateral ventricle or the surface; and in a third case the seat of the hæmorrhage was quite exceptional, being the interior of one occipital lobe.

In twenty-four consecutive fatal cases of cerebral hæmorrhage under the writer's care, death took place under twelve hours in seven, under twenty-four in eleven; on the second or third day in three; on the fourth, fifth, or sixth in eight; and on the ninth in two.

An apoplectic attack does not necessarily prove fatal. In many cases consciousness is regained. This always takes place more or less gradually. After a few hours one is perhaps able to rouse the patient so that he will give his name, although when left to himself he still takes not the slightest notice of anything that goes on in the room. For several days he generally remains drowsy and apathetic, or his ideas may be confused and perplexed; or he may even be delirious, talking incoherently, and throwing himself out of bed. In such cases, however, the prognosis is not good, in spite of the fact that the coma has passed off. Nothnagel says it is exceptional for recovery to occur if insensibility persists for as long as forty-eight hours. In cases which terminate favourably, as the patient regains consciousness the symptoms of local damage to the brain become manifest, of which the most important is hemiplegia, with or without aphasia.

Onset.—The older writers laid great stress upon certain symptoms which they believed to be frequent precursors of apoplexy, and which they therefore designated "warnings" or "molimina." But under these names they included a great variety of complaints, without any definite limits as to time: —epistaxis, for instance, happening several months before the cerebral attack; or an ecchymosis of the conjunctivæ, perhaps the result of a violent effort in coughing or sneezing; or even the frequent recurrence of giddiness or headache in a person advanced in years. These last symptoms, indeed, are not unlikely to be due to a morbid condition of the blood-vessels of the brain, which may presently lead to their rupture; and the local patches of softening, which we have seen to be more direct effects of such vascular changes, afford a ready explanation of other nervous disorders—such as thickness of speech, diplopia, partial ptosis, sensations of numbness and formication in the hand, or in the fingers, partial loss of power in the arm, or dragging of the foot,—any one of which, if occurring in an old man or woman, is pretty sure to be taken as threatening the supervention of an apoplectic seizure, even though it may after a few weeks disappear, leaving the patient apparently as well as ever. One cannot altogether reject this view of the matter; but it is to be remembered that each of the symptoms in question may arise from other causes, and that even if one could be sure that they were due to a diseased state of the cerebral arteries it would not necessarily follow that apoplexy was about to occur.

On the other hand, the very same symptoms may be actually results of cerebral hæmorrhage, a vessel in the brain having already given way; and, unless the extravasation remains small in amount, the patient is very likely to become comatose a few hours later. In such cases it is obviously incorrect to speak of "warnings."

Abercrombie, many years ago, pointed out that cerebral hæmorrhage comparatively seldom leads to sudden loss of sense and motion, or (in other words) to the classical form of apoplectic seizure. A precise clinical history of the cases in which extravasation of blood is most apt to be found is given in his celebrated work. The first symptom, he says, is a pain in the head, which may be so violent as to make the patient scream. The face

at the same time becomes pale, the body cold, and the pulse very weak; there is sickness, or even vomiting; and he may fall to the ground faint and exhausted. Often a slight convulsion occurs. After a little while he may be able to walk home; he is quite sensible, but oppressed; he remains cold and feeble, with cadaverous pallor of the countenance. By degrees he recovers his warmth, his face regains its natural appearance, and his pulse improves in strength. Then he becomes flushed, he answers questions slowly, and gradually he sinks into coma, from which he rarely recovers.

All subsequent writers have recognised the truth of this picture. After fracture of the skull, when the middle meningeal artery is torn through, there follows a very similar series of events; and the name of "ingravescent apoplexy" has been given to cases which run such a course. But, until recently, most observers have regarded this as only one form of the disease, and have supposed that cerebral hæmorrhage often begins with sudden coma. Now, it is true that the patient is frequently insensible when first seen. Perhaps he is picked up in the street, or found lying on the floor, or in a water-closet; or the seizure may have come on during sleep, so as to give no opportunity of tracing its earlier symptoms. But Trousseau says that although his attention was for fifteen years directed to the question, he did not in that time meet with a single instance in which, when an attack of cerebral hæmorrhage occurred in the presence of witnesses, it did not begin more or less gradually. An exception must be made for those rare cases of hæmorrhage which destroys life in a few minutes (p. 580). Another exception is allowed by Trousseau himself for certain cases which begin with an epileptiform seizure, and this is endorsed by Dr Hughlings Jackson, who has laid special stress upon the frequency of this mode of commencement. But "ingravescent apoplexy" is no particular modification of the disease; it is the rule in cases of large cerebral hæmorrhage.

Moreover, it must be admitted that the symptoms before coma sets in are more variable than would appear from Abercrombie's description. Pain in the head is often absent. Not infrequently the only thing which is noticed by the patient is a numb feeling, or a sense of weight in one of the limbs. Thus Trousseau relates the case of a woman who while returning from market noticed that she dragged her right leg, and that her right arm felt heavy, so that she changed into her left hand a folded newspaper which she was carrying, lest it should fall into the mud. She walked upstairs into her room, took off her clothes, and got into bed; after which she became hemiplegic and comatose, and remained in a state of stupor for three days. Another patient of Trousseau had noticed while at dinner that one of his hands felt heavy; he was not giddy, but faltered a little in his speech. He tried to rise from his chair, but one of his legs being paralysed he fell down. His children lifted him up, and with their assistance he walked into the next room. Trousseau arrived in three quarters of an hour, and found him perfectly conscious; but his left arm and leg were almost powerless. Profound coma set in in a few hours, and he died the next morning.

Another modification of the early symptoms produced by cerebral hæmorrhage is marked by a transitory loss of consciousness, from which the patient quickly recovers, so that it is separated by an interval from the final coma. To this Trousseau gives the significant name of "cerebral surprise." A satisfactory explanation is not easy. We must suppose the injury to the brain at the moment when the vessel gives way causes a shock that is diffused over the nervous centres. Trousseau cites, in illustration, the expe-

riment of trephining the skull of a dog or rabbit, and introducing a leaden ball into its interior; symptoms of stupor, he says, are immediately manifested, which quickly pass off, leaving a degree of hemiplegia proportionate to the compression. But Nothnagel says that in hundreds of observations upon animals, in which he injected chromic acid into the brain, or produced artificial extravasation of blood, he never saw such an effect produced. He refers to the analogous effect of suddenly cutting through the spinal cord, in instantaneously suspending for a time the reflex excitability of the centres below the line of section (cf. p. 432).

Locality of the lesion.—Speaking generally, the most probable seat of cerebral hæmorrhage is the most common one—the region of the corpus striatum. If a second or third attack has proved fatal there is very likely ventricular hæmorrhage. If death has come on unusually rapidly there is probably either moderate effusion in the pons, or a very large one on the surface, or into the ventricles.

The fact that lesions affecting the cerebral convolutions so often give rise to convulsive seizures has led some observers to suppose that such symptoms are especially apt to occur in cases of *meningeal hæmorrhage;* but our cases do not bear this out. Nor is rigidity of the limbs noted as having been commonly present—a fact which Dr Goodhart pointed out in the 'Guy's Hospital Reports' for 1876; but it does seem that a definite hemiplegia is comparatively seldom observed in this form of apoplexy; the blood makes its way too easily along the subarachnoid space at the base of the brain to compress one hemisphere more than the other. In some cases the coma is preceded by delirium.

A curious question is, whether it is possible to make out at the bedside the existence of extravasation into the *lateral ventricle* when the original lesion is in one of the basal ganglia. The recurrence of coma, after recovery from a first seizure, has been attributed to this cause by Nothnagel and some other writers; but we have seen that it is common in all cases of apoplexy. Others have supposed that the presence of ventricular effusion is indicated by paralysis of all four limbs succeeding to hemiplegia, or by early rigidity of the arm and leg on the side opposite to the lesion. The latter opinion was maintained by Durand-Fardel. But probably the exceptional cases in which profound coma and death are caused by a clot limited to the substance of one hemisphere do not differ from those of extravasation into the ventricle. In 1874 the author made an autopsy in the case of a lad, aged seventeen, who had died fifteen hours after having been found lying on the ground, unconscious. All the cavities of the brain, including the third and fourth ventricles, were full of clot, which was in equal abundance on the two sides. No cause for the hæmorrhage could be found; but there had been repeated epileptiform fits. In 1876 an old woman died in the Clinical Ward of Guy's Hospital of a seizure which was unattended with paralysis of the limbs. The right lateral ventricle was full of clot, which had come from the superficial part of the caudate nucleus, the internal capsule being quite uninjured. Thus the absence of hemiplegia is not peculiar to cases of meningeal hæmorrhage.

In apoplexy of *the pons* the pupils are often contracted to pins' points, and the respirations are exceedingly infrequent—perhaps not more than six or four in the minute; but in one case dilatation of the pupils was present, and the breathing is sometimes hurried and irregular. Nothnagel seems to think that convulsions are more apt to occur than when blood is effused

into other parts of the brain; but this seems to be doubtful. Other symptoms enumerated are rigidity of the neck, tonic contractions of the limbs, vomiting, hyperpyrexia, and in rapidly fatal cases paralysis of the limbs on both sides. Crossed hemiplegia can seldom be made out satisfactorily while the patient is insensible. Hæmorrhage into the pons sometimes leaves behind it a permanent difficulty of articulation.

Diagnosis.—In the diagnosis of apoplexy one has to bear in mind many morbid conditions with which it may be confounded; in scarcely any other disease is it more important or more difficult to form a right judgment. The liability to error arises in two different ways: sometimes from the absence of any history as to the origin of the attack, or from the history being vague or untrustworthy; sometimes from the doubtful nature of the symptoms.

Thus a man may be discovered comatose and stertorous in bed or upon the pavement of the street, and there may be no one to say what has happened to him; or it may be impossible to depend upon the statements of those in whose company he is found; or there may be suspicion of foul play. In all such cases the following possibilities must be taken into careful consideration before deciding that the case is one of apoplexy: (1) that his brain has been injured by external violence, as by a blow or a fall, with or without fracture of the skull; (2) that he may have taken poison; (3) that he may be intoxicated; (4) that the coma is due to pyæmia, to uræmia, to diabetes, or to the effects of an epileptic fit.

1. As regards *injury to the brain*, difficulties arise in several ways. There may be no bruise upon the face or head, and no displacement of any part of the calvaria, so that it is only at the autopsy that we discover that the skull is fractured, or that the prominent parts of the brain on one side are bruised in such a way as to show that external violence had been the cause of death. Even then, however, one is by no means justified in concluding that the case was originally one of accident or of injury inflicted by others. The man may have had a fit or been drunk, and in falling he may have fractured his skull. Thus in 1859 a man was admitted into Guy's hospital who was driving in a cart, when he fell and was picked up insensible. He died after four days, and the surface of the brain was found to be extensively bruised; but as he was known to be subject to epilepsy, it appeared clear that one of these attacks had been the cause of his falling. We must bear in mind that meningeal hæmorrhage often occurs as the result of disease; it is, therefore, only when the brain-substance itself is ecchymosed that we are justified in attributing to external violence cases in which blood is found effused on the surface of the brain. On the other hand, we have had several instances in which a severe injury of the skull with laceration of the cerebral convolutions has been associated with hæmorrhage into the central parts, exactly like that which occurs in apoplexy. Some of these have undoubtedly been examples of spontaneous effusion of blood into the brain, the superficial injuries having been caused by the patient's falling upon a kerbstone or a hard floor, or the like, but it is certain that a blow or fall upon the head may in rare cases cause rupture of an artery in the interior of the organ. Thus in 1866 a man was admitted into a surgical ward an hour before his death who had been steering a barge on the Surrey Canal, when a steamer came too close and struck the rudder; the tiller knocked him over, and he was picked up insensible. There was no injury to the cranium, nor to the surface of the

brain. The right lateral ventricle was found full of effused blood, the septum was broken down, and there was a moulded clot in the fourth ventricle. In 1868 a patient in the ward for ophthalmic cases, being unable to see, missed his footing and fell, striking his left temple. A large quantity of blood was effused upon the cerebral convolutions, but the right corpus striatum was also extensively ecchymosed, and had in its interior a mass of blood of the size of a hazel-nut. In 1870 a man came to the hospital with a cut on his forehead, saying he had slipped upon a flight of stone steps at the Victoria Theatre. He ultimately became hemiplegic and comatose, and died, and the right lateral ventricle was found to contain a large clot, the blood having oozed from a rent in the thalamus. In 1855 a patient was admitted who had been found lying by the side of a crane, the handle of which seemed to have struck him on the head, there being a wound of the scalp. At the autopsy the left corpus striatum and thalamus were found to be destroyed by a large mass of blood lying between them.

Sometimes it is impossible to decide between injury and disease. In 1862 a man was admitted who had fallen several feet upon his head from a platform on which he had been working. His skull was found fractured, but the lateral ventricles were full of blood, and the right corpus striatum was broken up by a large clot which projected through an opening in its surface. His fellow-workmen thought he had overbalanced himself, as he had shown no sign of having a fit; but Dr Wilks, who made the autopsy, left the question open in his report.

It will be noticed how closely the appearances found in these five cases resembled those of spontaneous cerebral hæmorrhage. In the reports of three of them it is distinctly stated that the kidneys were granular, or wasted, or cystic. So that, although the rupture of the artery was the direct result of a blow or fall in each instance, it seems that they may fairly be regarded as examples of ordinary apoplexy, the main cause having probably been indirect, namely, the existence of chronic disease in the coats of the vessel. Most likely, if no accident had happened, these patients would have died of spontaneous hæmorrhage into the brain a few weeks or months later. One cannot be surprised that it is impossible to diagnose such cases in the absence of a history during life, when the right interpretation is so difficult after an autopsy.

2. Narcotic *poisoning* may be mistaken for apoplexy, or *vice versâ*. We have seen that in some instances in which blood is effused into the pons the pupils are contracted and the respiration is regular and very infrequent, just as in persons who have taken large doses of opium. The author was summoned one night to see a lady some six or seven miles away from London, and found her comatose, with the symptoms just mentioned. There was a suspicion that she had poisoned herself, for the day was the anniversary of the death of a son; and a few hours before her illness began she had said to a sister, who had come to visit her, "Well, have you come to see me die?" But she had been sitting up in bed talking to this sister, and apparently as well as usual, when she suddenly fell back comatose. This fact appeared to exclude the possibility of her having taken opium; and the conclusion seemed clear that there was hæmorrhage into the pons. But the next morning she was quite well again, and never confessed that she knew the cause of her illness. The case shows that a patient deeply comatose from opium *may* recover without being walked about or swallowing strong coffee

or stimulants. In one case of suicide from prussic acid, recorded by Dr Stevenson ('Guy's Hosp. Rep.,' 1869), death did not occur for more than an hour and a quarter after the discovery of the fact that the poison had been swallowed, and the symptoms could not have been distinguished from those of apoplexy; but all difficulty was removed by the fact that there was on the table a half-empty, although corked, bottle containing some of the poison. A marked odour of prussic acid was diffused through the room, but the patient's breath seemed not to smell of it.

3. It is often difficult, and sometimes impossible, to distinguish apoplexy from *alcoholic intoxication*. A man who really is dead drunk may be supposed to have cerebral disease; but the only result likely to follow this mistake is that a patient who had been expected to die, or at least to become hemiplegic, may in a few hours completely recover. In 1868 a boy, aged fourteen, was admitted into Guy's Hospital, who with another boy had stolen two bottles of brandy, and, according to his companion's statement, had drunk a reputed quart (twenty-six and two thirds fluid ounces) without any admixture with water. This occurred at about 2.15 p.m.; by four o'clock he was insensible, and he was at once taken to the hospital. He was completely insensible, but without stertor; his pupils were at first of natural size, but they afterwards became contracted. An œsophageal tube was passed, and the contents of the stomach were pumped out, with a most powerful odour of brandy. He was then put to bed, and an enema of coffee was administered. He remained unconscious for twelve hours; then he asked for a glass of water, and before long was well. Dr Stevenson, commenting upon this case in the 'Guy's Hosp. Reports' for 1869, says that no doubt the boy owed his recovery to the prompt use of the stomach-pump.

It very rarely happens that anyone swallows a fatal dose of alcohol except for a wager or out of bravado, when the medical man who is called to the case is sure to be told of what has occurred, and to mistake intoxication for apoplexy is to commit an error which is scarcely ever likely to be injurious to the patient, even though one should omit to use the stomach-pump. On the other hand, to suppose that a man who has apoplexy is merely intoxicated is a most serious matter. This is the mistake which is often made by the police, and into which medical men themselves have too often fallen, from failing to appreciate the real difficulties in the diagnosis between the two conditions. Perhaps the patient is found in a public-house, or is known to have been drinking heavily, or smells strongly of spirits. The only safe course for us is to ignore these facts altogether. The odour of brandy, does not even prove that any stimulants have been taken before the attack commenced; it may have been administered afterwards. The only safe rule, which should never be departed from, is that a man who is insensible, and who cannot be roused, is never to be sent away to the police station, nor be left by himself to sleep off the supposed drunkenness. He should always be put to bed and carefully watched. The presence of convulsions, hemiplegia, or inequality of the pupils may make one certain that the case is due to something beyond alcoholic intoxication; and the same conclusion may be drawn, although with less confidence, from the occurrence of rigidity of the limbs, or of stertor; but the *absence* of any or all these symptoms is no disproof of cerebral disease.* The most

* It would seem that by testing the urine one can obtain positive evidence that a poisonous dose of alcohol has been swallowed. According to Anstie, this inference may be drawn if to fifteen drops of his chromic acid solution (made by dissolving one part of

important cases, however, are not those in which coma, or even partial unconsciousness, is present, but rather those in which the patient is noisy and excited, grimacing and throwing his limbs about; one is perhaps sure that such a man is drunk, but it may be impossible to say whether or not he also has hæmorrhage going on within his skull. Rupture of a cerebral artery seems often to be the direct result of indulgence in drink, and to detect its early symptoms must obviously, in such circumstances, be exceedingly difficult. Medical men who have had the largest experience are those who most freely acknowledge the impossibility of speaking confidently, particularly when the patient is advanced in years, and may have chronic disease of his heart, or of his kidneys and cerebral arteries.

4. Even when we have decided that a patient who is comatose is not suffering from an injury to the head by external violence, nor from narcotic poisoning, nor from the effects of alcohol, there are still some other questions to be considered, though of subordinate importance, before we can safely conclude that he has apoplexy as above defined (p. 578). One possibility is that the case may be one of *pyæmia*, or some other specific febrile disorder. The author saw two cases in each of which a profound and rapidly fatal coma was proved by the autopsy to be due to this cause. One was that of a man, aged twenty-six, who was brought to the hospital insensible, and died in a quarter of an hour. Very little could be learnt about him; but it was stated that he had recently arrived on board ship in the port of London, and that he had been giving evidence in a court of law on the day of his death. The brain appeared healthy; but there was suppurative inflammation of the peritoneum, and also of one knee-joint. The other case occurred in a girl eleven years old. She was admitted into the hospital one morning at half-past six, and, immediately after being put to bed, she gave one gasp and died. Her mother said that she had been quite well until the previous day, when she complained of pain in the left side on returning home from school in the afternoon. She went to bed, and fell asleep; but at 4 a.m. (two hours and a half before her death) she was found to be unable to speak, and to be rolling over and throwing her arms and legs about. When brought to the hospital she was unconscious, and was breathing heavily with froth upon her lips; the right pupil was dilated, the left contracted. The temperature was 101·2°, the pulse 116, the respirations 32 in the minute. All that could be discovered at the autopsy was that the surface of the right lung was ecchymosed, and that there was a partial hepatisation of the lower lobe of the left lung, with much lymph effused on the pulmonary pleura over a circumscribed area. The probable interpretation of these cases is that there was some early change in the brain so intense as to kill before it could be recognised by the naked eye. We shall see that tubercular meningitis may prove fatal at a stage when the microscope is required to demonstrate its presence.

5. Another possibility is that the coma may be due to *uræmia*. The older pathologists were familiar with cases in which, finding no blood effused upon the brain, they were driven to suppose that the cerebral symptoms which had proved fatal were due to the presence of fluid in the ventricles and beneath the arachnoid; and they described the affection under the name of "serous apoplexy." At the present day, however, this name, and the idea on which it was based, have alike fallen into oblivion.

bichromate of potass in 300 parts by weight of strong sulphuric acid) one drop of urine is added and turns immediately of a bright emerald-green colour. In the case of the boy who was under my care in 1868, it took two drops to produce this effect.—C. H. F.

Several years ago Dr Wilks suggested that the majority of the cases in question were examples of Bright's disease; and his opinion has been endorsed by all later writers. But in reading the detailed clinical reports given by Abercrombie it is far from clear that the cause of death in his cases was uræmia, rather than some one of the less obvious cerebral lesions which at that time would have escaped recognition; and there seem to have been few cases at Guy's Hospital in which the symptoms were like those of an apoplectic attack, and in which the only disease that could be discovered at the autopsy was in the kidneys. On the other hand, it has often happened that albumen has been detected in the urine of a patient who had been brought into the ward in a state of insensibility, and uræmia diagnosed, until a *post-mortem* examination showed that the coma was due to cerebral hæmorrhage. The common occurrence of albuminuria in such cases is partly due to the frequency with which the kidneys are found to be granular; but albuminuria is often met with in apoplectic patients whose kidneys are afterwards proved to be perfectly healthy; so that it is probably to be regarded as a result of venous congestion.

Among the few instances in which an apoplectiform seizure has been found at Guy's Hospital to have been caused by renal disease, without any cerebral lesion being discovered, the following may be cited.

In 1867 a man, aged forty-eight, was brought to the hospital, conscious, but unable to speak; his friends said that he had often suffered from headaches; the day before his admission he complained that his mind was wrong; his manner was strange, but he answered when spoken to. Afterwards he became insensible, passing his excretions under him. At one time he regained his senses sufficiently to say "yes" and "no;" and he could swallow; but he soon relapsed into coma, and died on the following day. His pupils were rather contracted, and his breathing was laborious. The brain was found pale and anæmic; the ventricles were nearly empty. The heart was hypertrophied; the kidneys were extremely wasted, as a result of dilatation of the calyces secondary to stricture of the urethra.

In 1868 a man, aged forty-four, who had been intemperate and gouty, and who had been suffering from a severe headache for a fortnight, was brought to the hospital in a drowsy state, from which he could just be roused to speak. He had had a fit, and had bitten his tongue. His body and limbs were in a state of constant jactitation. His pupils were rather contracted. His urine was retained, but his fæces were passed into the bed. Before his death he had two more fits. The only changes found in the brain were that it was tough and wasted, with large ventricles, and with an excess of fluid in them; but the kidneys weighed only two ounces and a half, and were exceedingly granular. At the bedside it would probably have been impossible to say, in reference to either of these cases, that an artery had not given way within the brain.

It has sometimes happened that patients already under treatment in the hospital for Bright's disease have died quickly with cerebral symptoms; but under such circumstances hæmorrhage is comparatively infrequent. In the immense majority of cases the stupor caused by uræmia alternates with convulsions, and passes off again and again without leaving hemiplegia—so as to prove that no structural damage has been done to the brain.

6. Coma from *diabetes* or from *cholæmia* may simulate apoplexy, but the presence of glycosuria or of jaundice will decide the nature of such cases.

7. Of cerebral diseases, the one which is most likely to be mistaken for

apoplexy, is a form of *epilepsy* which was described by Andral and other French writers as a separate malady under the ponderous name of "apoplectiform cerebral congestion," until Trousseau pointed out its real nature and distinguishing characters. In all probability Abercrombie would have included it under what he termed "simple apoplexy," in which after death no morbid appearance could be discovered in the brain. Sir William Gull in his lectures used to teach that "simple apoplexy" was nothing but epilepsy; but a careful perusal of Abercrombie's cases leaves one doubtful whether all of them can be fairly interpreted in this way, and whether, if precisely similar ones were to occur now, the more accurate pathological methods which we possess would not enable us to place them in different categories. The question, however, is not of any practical importance.

Among the cases related by Trousseau are the following:—In 1845 a gentleman, aged forty-two, was found in his bed insensible; his face was turgid and livid, there was stertor, and all power of motion and sensation was lost. How long he had been in this condition his wife could not tell—she had been awakened by a strange snoring noise. Trousseau had the patient placed in a half-sitting posture, threw cold water in his face, and applied ligatures round the upper part of the thighs to retain the blood in the legs. Scarcely one hour elapsed before he regained his senses and the use of his limbs, and on the following day great lassitude was the only remaining symptom. Some time afterwards the same physician was fetched in great haste to a neighbour, aged seventy, who was said to have been attacked with apoplexy on the Boulevards. He had been unconscious for a quarter of an hour, but was recovering his senses when Trousseau arrived. He did not at first recognise him, and looked vacantly round, throwing his arms and legs about without knowing what he was doing. Within a few hours, he gradually and completely recovered, although no active treatment was used.

In both instances the real nature of the disease was afterwards established by the recurrence of the seizures at more or less frequent intervals, attended with all the symptoms of epilepsy. Indeed, it must be observed that in each case the attack began when no skilled observer was present, so that there is no proof that convulsions did not occur. And Trousseau himself goes on to say that in almost every instance of the same kind in which he was consulted, and in which the commencement of the seizures had been seen, "nervous twitches" or convulsions had been present. Thus, after all, the identification of "apoplectiform cerebral congestion" with epilepsy involves little more than the recognition of two facts—that the spasms which usher in an epileptic seizure may be but slightly marked, so as to escape the notice of a non-professional observer; and that when one is called to a patient who is comatose one must make sure that the disease is *not* epilepsy before committing oneself to a diagnosis of apoplexy. In determining this latter point, we must first ascertain whether the patient has ever before suffered from seizures which could have been epileptic.

The author was one evening called out in great haste to see an old man, and found him lying on the sofa in his sitting-room, comatose and stertorous, with puffing cheeks and a purple countenance. His pupils were dilated, but the general aspect suggested positive apoplexy, had not his housekeeper, who had found him insensible, known that he had once or twice before had epileptic attacks. Before long he completely recovered. One of Trousseau's cases is that of a solicitor, aged thirty-five, who was sent to him from

the country, with the history that in the course of the previous six months he had had three apoplectic fits. They had lasted, however, an hour at the most, and they had left no paralysis behind them. Trousseau accordingly declared the disease to be epilepsy, and his diagnosis was before long found to be correct. But of course there must in every instance be a first attack, and then the criterion fails, and if this seizure should prove fatal the real nature of the disease must remain a matter of inference. In 1865 a man, aged sixty-seven, a tanner in Bermondsey, was brought into the hospital comatose and died in a few hours. He had followed his occupation until the day of his death, when he was found insensible, having fallen to the ground. He had convulsive movements and appeared to be paralysed on the right side. It could not be ascertained that he had ever before had a similar attack, but he was said to have suffered much with his head. No recent morbid change could be found in the brain, but there was chronic wasting, the convolutions being shrunken, with much fluid in the sulci, and the ventricles being enlarged and their surface granular; the skull also was dense and had no diploë, and the membranes were thickened and opaque.

A very similar case occurred in 1876. A woman, aged sixty-two, was brought into the Clinical Ward, having fallen down in the street in a fit. The right pupil was larger than the left. There was right hemiplegia, with complete anæsthesia in the right arm and in the right side of the face. After a time she partially regained her consciousness, but had several convulsive attacks. The coma then again became deeper, and she died at the end of five days. No morbid change could be found in the brain except wasting with dilatation of the ventricles; and there was only slight wasting of the kidneys.

There appears to have been no marked engorgement of the cerebral vessels in these instances; but from the way in which death is brought about it is evident that in similar cases such a condition is very likely to be found. May not some of the cases which Hammond and other writers describe as fatal "congestion of the brain" be really epilepsy?

There is a further criterion by which we may often distinguish an attack of epilepsy from one of apoplexy, and on which Trousseau has laid special stress—the mode of onset of the coma. We have seen that it is rare for a man attacked by cerebral hæmorrhage to fall down suddenly, deprived of sense and motion, and to remain persistently comatose. There are, indeed, cases in which apoplexy begins with a fit which is perfectly epileptiform in character; of this the writer saw a marked and repeated example, due undoubtedly to cerebral hæmorrhage; but such cases are exceptional. The practical rule, therefore, is that if we are informed that the commencement of a seizure was gradual, we may safely conclude that the case is not one of epilepsy; but if it began suddenly, we may often feel doubt as to its nature. In such a case our prognosis must be most cautiously guarded; a few hours later the patient may be apparently as well as ever, or he may be dying.

8. Several of the *organic diseases* of the brain may occasionally give rise to a rapidly fatal attack, resembling an apoplectic seizure in its symptoms. This is the case, for instance, with cerebral *abscesses* and *tumours*, and occasionally with tubercular *meningitis*. Sometimes, indeed, cerebral hæmorrhage does really occur as a complication of the softer forms of tumour, the blood-vessels within the growth giving way, and pouring out a large quantity of blood. It is not improbable that in many of the cases in which hæmorrhage has been found in the cerebellum, or in some other

unusual seat—the patient being perhaps young and the arteries healthy—the original disease has been a soft tumour of small size, which has been torn up by the extravasated blood and overlooked at the autopsy.

Diagnosis between the anatomical causes of apoplexy.—We now come to the differential diagnosis of the several lesions, which are each capable of causing apoplexy, aphasia, or hemiplegia; namely, hæmorrhage, embolism, and thrombosis; softening from syphilitic disease of the arteries may be separately considered.

The diagnosis of cerebral hæmorrhage from embolism and the allied lesions differs, according as the patient, immediately after a stroke, becomes unconscious (*apoplexy*) or retains his senses (*hemiplegia*).

(*a*) In cases of *apoplexy* we must be guided by such clinical cases as the following.

Cerebral embolism.—In 1868 a man, aged forty, was brought into the Clinical Ward with paralysis of the left side, having suddenly fallen down insensible while wheeling a barrow. He presently regained his senses and conversed about his symptoms; then he again became comatose, and remained so until he died a few hours afterwards. In 1869 a man was taken in for paralysis and partial anæsthesia of the left side; he was reported to have suffered from continuous headache for two or three weeks. A few days before his admission he had suddenly become giddy and lost the use of his left arm and leg; afterwards he was unconscious for two or three hours. In the same year a woman, who was in the hospital suffering from dropsy, had a fit which was followed by aphasia and right hemiplegia, and she died within two days. In 1874 a woman, who was in the ward for uterine cases under Dr Braxton Hicks, became comatose with left hemiplegia, and remained insensible until she died on the following day.

In none of these four instances was there any hæmorrhage into the brain, nor any change beyond softening of the part which should have received its supply of blood through the obstructed vessel. Yet, if no autopsies had been made, these very cases might well have been quoted as illustrating the chief varieties in the mode of onset of an apoplectic seizure due to the rupture of a cerebral artery. Nothnagel, indeed, states explicitly that there is no absolute difference between the symptoms of embolism and those of hæmorrhage; and there can be no question as to the inadequacy of certain points of distinction suggested by earlier writers—that in embolism the face is pale rather than red; and that cases of hæmorrhage are accompanied by excessive pulsation of the carotids, stertorous breathing, and inequality of the pupils.

Nothnagel quotes Dr Eliza Walker as having shown in her inaugural dissertation at Zürich in 1872 that embolism is very often ushered in by an epileptiform attack; this was the case in twenty-four out of ninety-seven cases which were collected by her. Nothnagel adds that embolism can never have any prodroma; but the statement is contradicted by one of the cases already cited, in which the attack was preceded by headache for two or three weeks.

Among the cases of spontaneous *thrombosis of a cerebral artery* at Guy's Hospital there have been the following:—A man, aged forty-eight, was attacked with pain in the head a month before his death; he fell back insensible, with right hemiplegia; afterwards he could walk, but he ultimately became again semi-conscious and rambling in his talk. Another

man, aged thirty-five, was attacked with unconsciousness and paralysis of the left side six days before his death; he then had convulsive fits, in one of which he died. Apoplexy due to this lesion cannot be distinguished from that caused by cerebral hæmorrhage.

As regards *syphilitic* disease of the cerebral arteries, the cases related by Heubner in his monograph suffice to show how closely its symptoms may resemble those of rupture of an artery in the brain. In eight cases out of twenty-two collected by him the symptoms were ushered in by an attack of apoplexy. In some rapidly fatal cases the insensibility lasted until death. In others there was a transitory loss of consciousness, accompanied by hemiplegia, and followed after an interval by the supervention of coma from which the patient never again awoke; in other words, the clinical features of an "ingravescent" nature were closely imitated. Case 33, for instance, is that of a man who had suffered from headache and sleeplessness, and who one day after having appeared to be as well as usual in the morning, was found later on to be comatose and paralysed on the right side: he could at first be roused a little, so as to make an attempt to open his eyes; but afterwards the insensibility became more profound, the face flushed, the pupils immovable, and he died the next evening. Case 47 is that of a journeyman furrier, admitted into the Leipzig Hospital in a state of unconsciousness. He had been attacked on the previous day with paralysis of the arm; this came on gradually, so that he watched its progress upwards from the thumb to the shoulder, being then in perfect possession of his senses, and able to point out with his left hand how high the numbness extended at any particular moment. There are, however, comparatively few syphilitic cases in which the symptoms and course resemble those of cerebral hæmorrhage.

Thus we find that an attack of apoplexy is by no means necessarily due to the extravasation of blood in the brain. Omitting spontaneous thrombosis on account of its rarity, we have embolism and syphilitic arthritis as possible causes of precisely similar symptoms.

The diagnosis is based entirely upon collateral circumstances. *Age* is an element of the highest importance. In persons more than fifty years old one is seldom wrong in attributing an apoplectic seizure to hæmorrhage; and the younger the patient the greater the probability that one of the other two causes is in operation. To decide between them we must look for indications of cardiac disease on the one hand, and, on the other, for eruptions on the skin or fauces, enlargements of the testicles or lymphatic glands and nodes. It must not be forgotten that cerebral hæmorrhage may be an indirect result of embolism, by the formation of an aneurysm in the obstructed artery (p. 555). In most cases of this kind the primary disease is ulcerative endocarditis, and the embola possess septic characters; so that enlarged and tender spleen, or albumen or blood in the urine, may suggest the correct diagnosis.

Notwithstanding the caution expressed above (p. 558), the *presence of albumen* when combined with a low specific gravity of the urine, a hard pulse and signs of an hypertrophied left ventricle are of great diagnostic value, for these symptoms of chronic interstitial nephritis much increase the probability of a ruptured artery. If we find evidence of *retinal hæmorrhage* by the ophthalmoscope we feel almost certain of our diagnosis. A *gradual onset* of coma, with severe previous symptoms of pain, giddiness, &c., for a day or two, points to occlusion of an artery (probably syphilitic in a young

adult), and consequent softening. A sudden and profound attack is probably due to hæmorrhage.

A shock, like syncope, with revival and then torpor, gradually deepening into coma coming on within an hour, points almost certainly to hæmorrhage, checked by failure of the heart, and returning as the circulation improves.

Pain in the head, with hemiplegia and subsequent coma, suggests cerebral embolism, and in a young subject with a cardiac murmur makes it practically certain.

(*b*) In cases of *hemiplegia* the diagnosis between its several causes depends first upon the question whether coma was present when the attack of paralysis occurred. If so, the considerations stated in the last paragraph are applicable; and in proportion to the duration and the severity of apoplectic symptoms is the probability that there was rupture of an artery. On the other hand, if the seizure was unattended with any, even transient, loss of intelligence, the presumption is strongly in favour of its being the result of a mere arrest of circulation in some part of the motor tract. This may depend upon embolism of a cerebral artery, or upon syphilitic endarteritis. Arteritis deformans often leads to the formation of patches of white softening in the substance of the brain. One would have expected that a point of considerable diagnostic importance would have been the insidious and gradual commencement of hemiplegia due to arteritis. But experience scarcely bears this out; the attack is generally sudden. It is probable that the nervous elements continue to perform their functions up to a certain point, notwithstanding impairment of their structure; and that several of them at length suddenly and simultaneously give way, just as a rope will sustain a weight until the moment before the last strand breaks.

The discrimination of the various lesions of the brain that may give rise to hemiplegia depends on a careful study of the other nervous symptoms. We have already seen the diagnostic value of the association of *aphasia* with hemiplegia, as showing that the Sylvian artery is obstructed, whether by embolism, thrombosis, or syphilitic thickening.

It is probable that persistent *hemianæsthesia*, when associated with hemiplegia, points to hæmorrhage rather than to arterial obstruction. For such a combination of symptoms shows that the posterior third of the internal capsule is involved; and this lies towards the periphery of the area of distribution of the Sylvian artery (p. 553), so that it might probably be fed from another source if arrest of the blood supply were the cause of the hemiplegia. However this may be, most of the cases hitherto recorded, in which loss of sensation has been permanent, have occurred in old people, so that rupture of an artery was probably the cause of the symptoms. In the case referred to above (p. 564) the patient was seventy-one at the time of the first seizure. Among fifteen fatal cases collected by Veyssière in 1874 there is only one in which the patient was young, that of a girl, aged twenty-two years; in several instances, indeed, the lesion is described as having been a patch of *ramollissement;* but no details are given to throw light upon the cause of the softening.

On the other hand, *syphilis* is apt to affect several of the large cerebral arteries, simultaneously or in succession. It is therefore not surprising that hemiplegia dependent upon this cause is sometimes accompanied by a series of *incongruous* or *irregular* symptoms, which cannot be referred to a lesion

limited to any one spot in the brain. Thus there is sometimes complete paralysis of one or more of the cranial nerves, or the patient may regain the use of the arm and leg which were first affected; and subsequently he may be attacked with loss of power on the opposite side. This, indeed, is not in itself characteristic of the syphilitic affection; for old people with atheromatous vessels are very liable to have patches of softening develop themselves in the two hemispheres in succession, or to suffer from the effects of small hæmorrhages into both corpora striata in turn. But symptoms due to syphilis are more apt to be irregular in their locality and course than those which depend upon other causes; the patient perhaps becomes able to stand, or even to walk, and then after a few days relapses; and such changes may occur again and again.

Heubner lays stress on a peculiar *somnolent* condition, as indicating the presence of syphilis: the patient, he says, is half awake, half asleep; he lies with his eyes shut, taking no notice of anything, and refusing to answer questions; but when one tries to examine him, he resists and turns round in his bed. That such symptoms are comparatively rare in cases of embolism or of cerebral hæmorrhage is true; but they are common enough when the disease is a *tumour* or some other local lesion, and one must always remember that these affections may also give rise to hemiplegia, if they are so seated as to involve the motor tract.

There is, in fact, no one of all the organic changes to which the brain is liable that may not sometimes induce loss of power in the arm and leg on one side; beside *epilepsy*, *hysteria*, *chorea*, and some other neuroses which will be described in their place.

Conversely, it occasionally happens that affections of the cerebral arteries may run their course to a fatal issue without hemiplegia appearing. Such cases may be attended with headache, loss of memory, drowsiness, delirium, vomiting, thickness of speech, dysphagia, involuntary evacuations, and other symptoms, but none of them are characteristic.

Prognosis.—The gravity of a case of Apoplexy may be judged of first by the depth of the coma; the ingravescent cases are the worst, while gradual recovery of consciousness is of good omen. In cases comatose from the first, death frequently follows on the third day, but it may occur after a week or even longer; and, on the other hand, recovery may follow prolonged unconsciousness if the pulse and breathing are not seriously affected, and if the patient is not fed. Rise of temperature is a bad sign. So are early rigidity, convulsions of the paralysed limbs, flapping of the cheek in breathing, insensitive conjunctivæ, and increasing cyanosis. The longer coma persists the less hope there is. When consciousness is once restored, life is generally preserved for that attack at least.

Treatment.—(*a*) That the treatment of Apoplexy is unsatisfactory is universally admitted. There is no disease in which it is more difficult to estimate the effect of therapeutical measures of whatever kind.*

Rest is always essential; the patient should, if possible, be left in the room in which the seizure occurred; a mattress placed on the floor does perfectly well for a time. His head and shoulders must be raised, and he should be turned over on his side, so as to prevent the tongue from falling

* So Hippocrates: "To cure apoplexy when severe is impossible, and not easy when it is slight" ('Aphor.,' ii, 41).

backwards against the pharynx. In cases in which it is clear that death is impending one ought to abstain from all active treatment. No good can be done by the application of a blister to the neck, or of mustard plasters to the calves. A patient whose coma is so deep as to threaten his life cannot be roused by such means; and if he is capable of feeling, the irritation must surely be injurious rather than beneficial.

When the case appears not to be altogether hopeless, five or ten grains of calomel or two drops of croton oil should be placed on the tongue, particularly if there is reason to believe that there is an accumulation in the bowels; or an enema of turpentine may be given. One must be on the watch for the necessity of passing the catheter if the insensibility should last more than a few hours. Whenever there is serious difficulty of swallowing, the administration of food or drink by the mouth should be altogether forbidden, on account of the danger of its running into the air-passages and setting up pneumonia. No harm results from keeping an apoplectic patient for a day or two without nourishment; but if it is thought desirable, enemata of beef-tea or milk may be employed. The lips and mouth may be kept moist with a feather.

Bloodletting, whether by venæsection, cupping, or leeches, is now seldom practised. Sir Thomas Watson, indeed, speaks of patients so insensible as not to feel the puncture made by the lancet, who have yet emerged from their coma while the blood was flowing. But it may be fairly doubted whether in such cases the disease was not that "simple apoplexy" which is probably a form of epilepsy, and in which a spontaneous recovery of consciousness often occurs with unexpected rapidity. If the pulse be large and labouring, the face flushed, the carotid arteries full and throbbing, it may be thought right to bleed. But the majority of patients suffering from cerebral hæmorrhage are advanced in years and impaired in health, so that one hesitates to employ a practice which can be of service in lowering the pressure within the vessels of the brain only by its general effect on the circulation. In a younger person the coma may be due to embolism or to syphilitic arterial disease, when the maintenance of a vigorous cerebral circulation is essential to recovery.

There is, however, one particular set of cases in which it seems probable that judicious management may sometimes prevent a fatal issue; namely, those in which the symptoms of cerebral hæmorrhage are slowly ingravescent. When one is called to such a patient in the early stage (that of collapse), one should keep him absolutely recumbent, with head and shoulders raised, and he should be allowed neither to speak nor to move. The limbs may be warmed by friction with hot flannels, but the administration of brandy, and even of ammonia, must be rigidly abstained from. As reaction comes on, the question of bloodletting must be most seriously weighed. It is true that a rapid death almost always occurs, and that the autopsy generally confirms the opinion that the case was hopeless from the first. But it is possible that free venæsection, just at the time when the vigour of the circulation is being re-established, may, by lowering the pressure in the cerebral vessels, prevent further effusion of blood.

Hæmostatics, such as ergot, acetate of lead, or gallic acid, are not often prescribed; but Dr Bristowe assents to their employment, and one is certainly encouraged to try them by their apparent success in cases of hæmoptysis. Cooling lotions, or a bag of ice, may be applied to the head, if they do not disturb the patient.

When coma is due to Embolism, the only treatment is to keep the patient in a state of the most perfect quietude, so as to reduce to a minimum the activity of the nervous centres, deprived of their blood supply.

In cases of obstruction from Syphilitic arteritis, inunction of mercury should be commenced with the first cerebral symptoms.

(*b*) A person attacked with Hemiplegia without unconsciousness should for some days be kept in bed, and as free from all cares as possible. If advanced in years, or suffering under heart disease, he should be supplied with soup, beef-tea, milk, and perhaps a little wine.

A syphilitic patient should at first have rather a scanty diet while the proper treatment is being carried out: say a twelfth of a grain of bichloride of mercury, with ten or twenty grains of iodide of potassium.*

But in too many cases of Hemiplegia—whatever its cause may have been—the limbs remain more or less completely paralysed, in spite of the most judicious treatment. Recourse is then had to electricity, which undoubtedly is sometimes beneficial. The continuous application of a weak galvanic current to the head, as suggested by Remak, is said by Nothnagel to be occasionally followed by a decided increase of power and diminution of rigidity in the affected muscles. Not more than from four to twelve cells should be brought into operation; the poles should be gradually applied and withdrawn, and should never be suddenly reversed; they should be kept in position for not longer than three minutes at a time; whether they are both placed behind the ears, or one upon one mastoid process and the other upon the forehead, seems to be a matter of indifferenee. Other methods are to galvanise or to faradise the muscles. Dr Reynolds lays down the rule that little or no good can be thus effected if the muscles contract to the normal extent. But if the contractility is diminished, electricity will often in the course of a few weeks restore it; at the same time the muscles will become less wasted, and the previously cold limb will regain its normal temperature. By faradising the extensor muscles of the fingers, one may diminish contraction of the fingers into the palm. In general it may be stated that the application of electricity should not begin till two months from the hemiplegic seizure; that it should be at once left off if it causes headache, giddiness, faintness, sickness, or any unpleasant feeling at the epigastrium; and that the current should never be so strong as to cause pain, nor so long continued as to cause fatigue.

The disease cannot be influenced by drugs, though occasionally laxatives and sometimes hypnotics are required. Nor can one reasonably expect any benefit to result from baths at Gastein, Pfeffers, or anywhere else. To prevent a recurrence of the attack, temperance both in eating and drinking, a loose state of the bowels, and the avoidance of emotional and other excitement, both of mind and body, are the rational and probably the only measures to be advised.

* Heubner relates some remarkable examples of recovery of power in the paralysed limbs under the method of inunction. A striking case was that of a student, aged twenty-six, who after having suffered from headache and giddiness for some weeks was attacked one night with left hemiplegia during sleep. There were indurated glands in the neck and at each elbow, and a scar on the velum palati. At the end of a fortnight he was no better—feverish, prostrate, sleepless, and delirious; bedsores were forming, and spasmodic movements of the right arm had begun. Mercurial ointment was rubbed in for seven days, and then iodide of potassium was given in large doses. Six weeks later he was able to leave his bed, and little by little he regained power in his limbs. Several years afterwards Heubner found him perfectly well, except that he walked with a stick.

TUMOURS AND ABSCESS OF THE BRAIN

"The Eye is the Index of the Brain."

CEREBRAL TUMOURS—*Tubercle—Syphilitic gumma—Meningeal growths—Glioma and other neoplasms—Symptoms: headache and other cephalic symptoms—Vomiting—Temperature, pulse, and respiration—Optic neuritis—Localising symptoms—for the base—the cerebellum—the motor area and other parts—Diagnosis from hysteria, meningitis, &c.—Diagnosis between the several kinds of tumour—Prognosis—Treatment.*

CEREBRAL ABSCESS—*Ætiology—Anatomy—Symptoms: general and localising—Diagnosis—Course and event—Treatment.*

Red softening—Histology—Causes—seldom or never primary.

Inflammation of the brain.—In discussing in the last chapter the symptoms which often enable us to determine the exact seat of the lesions which cause hemiplegia and aphasia, we entered upon one of the most interesting parts of the study of cerebral diseases; but the study was incomplete, because lesions of the arteries rarely occur except in certain regions of the encephalon. There is, however, another important group of local organic affections which are under no such anatomical limitation, and it will be in every way convenient to take them next, so as to place the reader in possession of the chief points that must guide him in what is termed the *localisation* of diseases of the brain. The group of diseases which occupies this chapter is not a pathological one; for it includes syphilitic gummata, tubercle, new growths, and inflammatory changes leading to softening and abscess. They only agree in being sources of increasing local pressure within the skull; but this is clinically all-important, for they produce similar effects; and at the bedside one can often distinguish these several affections only imperfectly upon indirect or collateral evidence. We will begin with a brief account of the lesions which may be included among new growths, taking first *Tubercle*, secondly *Syphilitic Gumma*, and thirdly *Tumour*. Afterwards we will discuss their symptoms in common, their differential diagnosis, and their treatment. Lastly, *Red Softening* and *Abscess* will be described separately.

1. *Tubercle of the brain.*—The tubercular process may affect the brain in two different ways. Sometimes a number of minute tubercles grow into it from the pia mater, or are scattered through its substance along the vessels. This condition is always associated with meningitis, and will be described in the next chapter. In other cases there is a single caseating mass, which may reach a great size. Such masses have been called "solitary tubercles," "tuberculous tumours," and "tubercular nodules." In size they generally vary from that of a pea to that of a walnut; one of the biggest is a specimen in the museum of Guy's Hospital, which was received from Dr Hughlings Jackson by Dr Moxon. Sometimes they have a flattened base towards the pia mater, but more commonly they are more or less

globular in form, and touch the surface only at one spot, or are completely surrounded by brain-substance. They do not adhere to the dura mater lining the skull, but sometimes may to the tentorium when they occupy the cerebellum. Their substance is of a bright yellow colour, firm, or even hard, opaque, and generally homogeneous, except that at the centre it may be softening down into a yellowish liquid, or may be partially calcified. But they also have, in most cases, a narrow, pinkish-grey, soft growing edge, which separates the yellow cheesy material from the brain-tissue around. This edge may obviously consist of an aggregation of miliary tubercles, but more often it has no such appearance. Microscopically it consists of corpuscles, which are sometimes larger than the lymphoid cells that characterise tubercles in other parts. Rindfleisch further insists on the fibrous texture of the marginal zone of the cheesy mass, and declares that many so-called cerebral tubercles are really non-tuberculous, deserving rather to be called fibroid tumours. But a similar transformation of the cellular elements of tubercles is well known to occur even in the lungs, so that there can be no doubt that these solitary yellow tumours of the brain are truly tuberculous.

Among thirty-two cases that have occurred at Guy's Hospital there were only two in which it is stated that no similar lesion could be discovered in any other part of the body. It is true that tubercular meningitis (which was found in several instances) would be regarded rather as an accidental result of infection from the caseous mass than as independent; but in a large number of instances there was chronic phthisis or disease of the mesenteric or mediastinal glands. In no less than eighteen of the thirty-two cases the cerebellum was the sole seat of the affection; three times it was the pons Varolii, once the medulla oblongata, six times one of the hemispheres: in the other four cases there were several tubercles in different parts of the brain.

Twenty-one of the patients were males, the remainder females, a proportion which accords with that given by other writers. In three instances the age was under five years, in six between six and ten years, in twelve between eleven and twenty years, in seven between twenty-one and thirty, in three between thirty-one and forty, and in one forty-two.

In one case, that of a child, aged four and a half, there is said to have been a fall upon the back of the head five or six weeks before the occurrence of a fit, which was the earliest sign of cerebral mischief; the seat of the tubercle was the pons. Dr Crichton Browne mentions ('West Riding Asylum Rep.,' ii) a similar instance; the same part of the head was struck, symptoms speedily showed themselves, and proved fatal in two months, and a mass of tubercles, the size of a walnut, was found in the cerebellum. If it should be thought that in the latter case there was hardly time enough for the development of such a lesion, a suggestion made by Rilliet and Barthez may apply, namely, that when an injury seems to have been the cause of a tubercle in the brain, it may, perhaps, have merely set up acute changes around a tubercle which was there before.

2. *Syphilitic gumma of the brain.*—This affection also is attended with the formation of a firm, dry, yellow, caseous material, which is not always easily distinguished from tubercle. One point of difference is the fact, long ago pointed out by Wilks, that it is constantly seated on the surface of the organ, growing into the cerebral substance from the membranes. Heubner states that an analysis of forty-five cases, recorded by different observers, yielded only three exceptions to this rule, and not one of these was conclu-

sive. Again, when a gumma occupies the convexity of the brain, or the summit of one of the cerebral lobes, the corresponding part of the dura mater becomes thickened and converted into a tough yellow layer and adherent, so as to form with it one inseparable mass. Thus the shape of a gumma is far more irregular than that of a tubercle, which we have seen to be more or less globular. Lastly, the syphilitic affection commonly shows a much more considerable proportion of translucent undegenerated tissue; this appears as a moist greyish-red or grey mass, which is sometimes as soft as jelly; it is especially apt to be abundant at the base, where it may involve several of the cranial nerves and fill up the sella turcica as well as the diamond-shaped space. Microscopically it consists of granulation-tissue, containing some spindle-shaped and stellate elements, and having (according to Heubner) a distinctly alveolar structure in many instances. It is very vascular, and sometimes presents many little extravasations of blood. On the other hand, if antisyphilitic remedies should have been freely administered during life, the only morbid change found after death may be a patch of superficial softening of the cortex, beneath a local adhesion of the dura mater to the brain; this was the case, for example, in a patient of Dr Dreschfeld ('Lancet,' 1877).

It is curious that of ten cases of gumma of the brain at Guy's Hospital all but one were in persons between the ages of thirty-one and forty, the exception being a patient of twenty-six. In five of them there was a definite history of constitutional syphilis, or else indisputable syphilitic lesions were found; only one patient distinctly stated during life that he had never had venereal disease, and in that case the liver contained gummata. As might be expected, males preponderated over females in the proportion of seven to three. In several instances the report of the autopsy is incomplete, an examination of the testes having often been omitted. In one case the patient's illness had been attributed during life to a sunstroke. This was, no doubt, a mistake, but many writers think that a blow or fall upon the head may determine the formation of a gumma in the brain. "Sunstroke" practically often turns out to be cerebral syphilis.

3. *Other tumours of the brain.*—There is no region of the body in which so many different kinds of new growth are found as in the brain and in its membranes; yet histological distinctions are nowhere else of so little practical importance, because the clinical history and symptoms of a case are seldom, and then but slightly, affected by the nature of the tumour. A brief description of the chief varieties will therefore suffice.

a. The *membranes* may present fibrous and some other simple tumours, such as occur almost anywhere, and malignant tumours of all sorts, primary or secondary. A favourite seat for malignant growths is between the dura mater and the bone; or perhaps it would be more correct to say that they begin within the osseous substance itself, and either push inwards the dura mater or penetrate it, protruding upon its inner surface, and invading the cerebral tissue. They generally are *sarcomata.*

Two or three kinds of innocent tumour are peculiar to the coverings of the brain. To one of them Virchow has given the name of *psammoma*, from its containing calcified particles, like those which constitute the brain-sand of the pineal body and choroid plexuses. The lime-salts are deposited in curious little globular structures, made up of elements arranged concentrically, so as to resemble somewhat the well-known "bird's-nest cells." Robin accordingly described this affection as a form of epithelioma; but such a view of

its nature is incorrect. Virchow says it generally appears as a semi-globular mass, of firm consistence, pale red or white, and medulla-like. One examined by the author had a loose texture and a flocculent surface; it grew in such a position as to indent the brain above the left Sylvian fissure. According to Virchow such growths are less frequently seated in the tentorium or in the falx than in the dura mater lining the skull—particularly at the fore-part of the base.

Another special form of tumour peculiar to the membranes is that which was formerly called a *cholesteatoma*, but which has of late been termed "pearl-cancer." It constitutes a dry, hard, rounded mass, occupying the pia mater generally at the base of the brain. Its cut surface has a pearly lustre, and it consists of lobules made up entirely of horny epithelial cells, and supported by a stroma of dense connective tissue.

Lastly, Virchow has described under the name of *melanoma* a fourth kind of meningeal new growth; in a case which came under his observation there were numerous black or brown nodules in the pia mater, the rest of the body being entirely free from them.

β. Of the tumours that have their seat *within the brain-substance* there is one kind that is almost peculiar to it, while the rest are like those found in other parts of the body.

Among the latter, *sarcomata* are the most numerous, especially those of the spindle-cell variety. Sometimes, though very rarely, a myxoma or fibroma is met with. Primary carcinoma of the brain is so rare that only one case in our records at Guy's Hospital is said to have been of that nature. Even secondary cancer is not common; in the majority of cases in which secondary nodules are developed within the cranium, the growth is a form of sarcoma. A peculiarity of secondary tumours in the brain is that they are almost always multiple. On the other hand, it is a rule to which there are scarcely any exceptions, that a primary new growth is solitary. Among forty-four cases collected from our records, in only two was there more than one tumour in the brain, without obvious source of infection elsewhere; and it is quite possible that in those cases there was primary disease of one of the bones, or of some other structure which was overlooked.

The centre of a cerebral tumour now and then softens down into a cyst, and this may become so large that the presence of any solid growth may not be obvious. We have at Guy's Hospital had five cases in which the cerebellum has contained a large thin-walled cavity, filled with a fluid that was highly albuminous or deposited spontaneously a fibrinous coagulum. In three instances no adventitious tissue could be discovered, except the vascular membrane forming the cyst itself; but in each of the other two there was a small tumour situated on one side of the fibrous wall. These cavities are more rare in the cerebrum than in the cerebellum ('Path. Trans.,' 1885, vol. xxxvi, p. 17).

Hydatids are of very rare occurrence in the brain. In a girl, aged nine, Dr Moxon found a large *echinococcus* occupying the middle and posterior lobes of the right hemisphere; she had also a similar affection of the liver. The *Cysticercus cellulosæ* sometimes infects the pia mater or the ventricles.

The one kind of tumour already alluded to as almost special to the brain* is that which Virchow termed *glioma*, because he regarded it as an overgrowth of the neuroglia, or interstitial connective tissue of the brain, which he dis-

* A similar affection sometimes occurs in the retina during childhood, and perhaps also in the suprarenal capsule.

covered to consist of a granular or faintly fibrillated matrix, in which are embedded small nuclei with scanty protoplasm. Such a growth is not very unlike a sarcoma; and many pathologists describe it as a mere variety of that form of tumour. Indeed, Virchow himself admitted that it was often impossible to say of a particular specimen whether it should or should not be called a sarcoma; and he expressly recognised the occurrence of intermediate forms, which he termed glio-sarcomata. But although the distinction may not be of great practical importance, it appears to rest upon a sound theoretical basis, inasmuch as the neuroglia is a completely developed or adult structure, whereas the elements of a sarcoma are embryonic, corresponding with those of connective tissue at an early stage of its growth.*

A glioma may be of a pinkish-red colour, or it may look so exactly like the normal brain-substance that the microscope is required to demonstrate its presence. Its substance is always continuous with that of the surrounding cerebral tissue; for there is never a capsule, as with some sarcomata. Indeed, it often assumes the form of the part in which it grows, so that one might imagine the corpus striatum or the thalamus, or some particular convolution, to have become swollen to three or four times its natural size. But in some cases extensive caseation takes place in these growths; and, according to Klebs, they are also liable to sclerosis, exactly like that which occurs in the normal brain-substance.

A soft glioma often contains a great number of thin-walled vessels, which may rupture and pour out blood into its tissue, tearing it up so that one can hardly discover any trace of the growth. As Virchow long ago pointed out, the disease may then be mistaken for a simple cerebral hæmorrhage.

Perhaps the most puzzling cases of all are those in which repeated extravasations occur, and in which the coagula become converted into tough opaque caseating masses of various colours.

Not only gliomata, but all the less circumscribed forms of cerebral tumour, are apt to set up in the adjacent brain-tissue morbid changes that can only be regarded as inflammatory, and as due to irritation caused by their presence. Such an affection sometimes assumes the form of "red softening." More often it is what Rokitansky first described as "yellow softening"—a state in which the medullary substance has a faint yellow tinge, and looks glistening like blancmange; but nevertheless retains its form when sliced or cut, and is not, in fact, softer than the rest of the brain. The microscope throws no light upon its nature, but it appears to be œdema. Another common result of the presence of a new growth in the brain is the accumulation of an increased amount of fluid in the ventricles, which may become greatly enlarged. It might sometimes be attributed directly to compression of the veins of Galen or of the choroid veins, as when the tumour is seated in the cerebellum or in one of the posterior lobes of the cerebrum. But Virchow has pointed out that hydrocephalus often occurs where this explanation is inapplicable; and his statement is confirmed by several cases in our records.

Statistics of cerebral tumours.—To judge from a series of cases that have

* Prof. Klebs, now of Zurich, maintains ('Prager Vierteljahrschrift,' 1877) that gliomata also contain newly formed nervous elements. Certain cells with many-branched processes, which are well known to occur in these tumours, are regarded by him as ganglionic cells; and he believes that they are sometimes developed out of the axis-cylinders of nerve-fibres.

occurred at Guy's Hospital, there is a remarkable difference in the liability of the several parts of the brain to be the seat of tumours at different ages. We have had twenty-two cases in which there was a primary new growth in one of the *hemispheres*, sixteen on the right side and six on the left. In only five of these was the patient less than thirty years old; the rest were pretty evenly distributed between the ages of thirty and sixty. On the other hand, out of fourteen cases in which a tumour was seated at the *base* of the brain, ten occurred in persons under the age of thirty. The six instances of cysts in the *cerebellum* were all in patients between twenty-one and twenty-seven years old. There were only two cases in which solid tumours were found in children under the age of ten; in each instance the seat of the affection was the cerebellum.

Tumour of the brain is more frequent in males than in females. Among forty-two cases at Guy's Hospital, in which the sex is recorded, the proportion is as 27 to 15. This corresponds very closely with the ratio of 10:6 given by Obernier; but it is interesting that in the cases in which one of the hemispheres was the seat of the affection the preponderance of males is much higher, namely, as 16 to 6; for men are much more liable than women to blows and falls; and Virchow has expressed the opinion that new growths affecting the upper parts of the brain are often caused by injuries to the head. He has further stated that tumours in this position are generally gliomata, whereas at the base sarcomata and carcinomata are more often found.

In the forty-third volume of the 'Guy's Hospital Reports' Dr Hale White collected 100 unpublished cases of cerebral tumour, which were found in the deadhouse from 1872 to 1884 inclusive. The new growth was tubercular in nearly half of these cases (45), and it was a glioma in 24. Two of the remaining cases were glio-sarcoma, 10 sarcoma, 5 carcinoma, 5 gumma, 1 myxoma, and 1 lymphoma; while 4 were cystic.

Of the tubercular cases, 34 occurred in male and 11 in female patients; more than half of these 45 patients were children under ten years old. The hemispheres were the seat of a tubercular tumour in 22 cases, the cerebellum nearly as often (20), the pons in 6 cases, the bulb and the crus cerebri in one each. Nineteen of the tubercular tumours were multiple.

Glioma was widely distributed among patients of different ages, from three years to sixty-two. Here also the male sex predominated in the proportion of 19 to 5, and all the patients under twelve were boys. The seat was the hemispheres in 13 cases, the cerebellum in 4, the pons in 2, the bulb in 1, the pituitarium in 3, and the dura mater in one only.

Of the four cysts, two were situated in the cerebellum. One of the cerebral cysts was a hydatid.

Considering locality only, 48 tumours of all kinds were in the hemispheres, 28 in the cerebellum, 10 in the pons, 7 grew from the meninges, 5 were in the basal ganglia, and 3 in the pituitarium.

Symptoms.—In proceeding to discuss the clinical symptoms of these various forms of cerebral tumour, we must first remark that in making *post-mortem* examinations one occasionally finds a tubercle or a tumour in cases in which there had during life been no suspicion of the presence of any cerebral lesion. Thus we have in the museum of Guy's Hospital a specimen of a very hard growth, nearly as large as a pigeon's egg, attached by a pedicle to the ridge of the petrous bone; it was discovered accidentally in

the body of an aged pauper woman who was said to have had no cerebral symptoms. Another preparation is one of a large carcinomatous mass in the cerebellum, taken by Dr Moxon from a patient who died of cancer of the breast and of the liver. But it may be said that, if she had lived a little longer, the tumour might have manifested signs of its presence; and the same remark applies to the very few instances in which one or more small tubercles have been unexpectedly found in the brain in persons who have fallen victims to phthisis or to some other scrofulous disease. All that is really proved by such cases is that lesions of various kinds may be latent during the early periods of their development. But of this fact there is abundant evidence of another kind. Thus when tubercular meningitis has been the cause of death, and when the patient had appeared to be perfectly well up to the time of the commencement of that disease, one not uncommonly finds one or more yellow tubercles in the brain-substance which must obviously have been of older date. Again, it sometimes happens that a person dies of what appears to be an acute illness, and that the only lesion found at the autopsy is a tumour, with softening of the surrounding cerebral tissue. Some years ago a man was admitted into hospital insensible, livid, and in a high state of fever, so that the diagnosis was typhus; he lived only three days from the time when he was first taken ill, but at the autopsy a small spindle-cell growth, of the size of a bean, was found projecting into the fourth ventricle from the side of the aqueduct. But, with the exception of one or two instances in which psammomata or other meningeal tumours have been quite unexpectedly discovered, our records do not appear to contain an instance in which a tubercle or a tumour has been met with in the brain of a patient killed by accident, or who died from some indifferent disease, such as heart disease, or ileus.

The symptoms may be divided into two groups. Some of them are common to the large majority of cases; others are comparatively seldom observed, their presence being dependent upon the seat of the lesion. It will be convenient to describe the former group of symptoms first; and they may be arranged under three heads:—(1) cerebral symptoms proper, such as headache, giddiness, epileptiform seizures, hemiplegia, loss of memory, mania, stupor; (2) disturbances of distant parts, including vomiting; (3) certain changes in the optic disc, which are revealed by the ophthalmoscope.

1. *Head-symptoms.—Pain* is very rarely absent, and is generally the earliest indication that anything is wrong with the patient. Its seat sometimes, but not always, answers to that of the lesion. The superficial nerves of the corresponding part of the scalp may be tender to pressure or percussion; or (as Romberg first noticed) the act of holding the breath or of coughing may increase the pain—no doubt by producing venous congestion. The museum of Guy's Hospital contains a large tumour, three inches in diameter, found many years ago in the left hemisphere of a girl, a patient of Dr Wilks, who had suffered severely from pain in the head, and who had declared that when she turned her head to one side she felt something move in its interior. Another preparation consists of a small growth from the dura mater, taken by Mr Day, of St. Neots, from an old woman who died of bronchitis. She had often expressed a wish that her head should be opened, because for years she had experienced anomalous pains in it, and a sense of coldness in one spot, not larger than a shilling; this corresponded very nearly with the seat of the tumour that was found after her death. The pain caused by a new growth may be of every degree of intensity, from a

dull headache to the most unbearable agony, such as is said to render a patient delirious. It is sometimes constant, but it generally undergoes exacerbation from time to time. In some cases, indeed, it is intermittent or paroxysmal, so that it may closely resemble ordinary migraine. Thus Abercrombie relates the case of a boy, aged six, who began to suffer from fits of severe sick-headache, recurring at first about once a fortnight, and leaving him in good health in the intervals. After five or six months the attacks assumed a different and more persistent character; and two months later he died, when a tuberculous mass was found in the cerebellum. A similar instance has been recorded by Lebert.*

Convulsions are frequently present, and sometimes most severe and frequent. It is not known whether growths situated in any particular region are more apt than others to be accompanied by general epileptiform fits, as distinguished from those seizures to be presently described as "Jacksonian epilepsy" which are limited to the muscles of certain parts, and unattended by loss of consciousness. Dr Reynolds was led by the examination of a large number of cases to the conclusion that convulsions were less common when the disease affected the anterior lobes than when it occupied the posterior lobes or the cerebellum.

Vertigo, varying from a slight feeling of giddiness on standing up, to reeling and inability to walk or stand upright, is an important symptom of a cerebral tumour.

Mental symptoms—including irritability of temper, depression of spirits, loss of memory, a general impairment of intelligence—may be observed even when a tumour lies in the membranes at the base of the brain. Thus we have in Guy's museum a specimen of a cholesteatoma, as large as a pigeon's egg, which compressed the under surface of the pons and cerebellum, and had also insinuated itself into the Sylvian fissure to some extent; the patient was at one time in the hospital with paralytic symptoms, but he became maniacal, had delusions, and was unmanageable, so that he was removed to Colney Hatch Asylum, where he died. On the other hand, the mental faculties are not infrequently retained nearly to the last when one of the hemispheres is the seat of the disease.

Friedreich and Obernier speak of excessive *sleepiness* as a principal symptom in two cases which severally came under their observation. The most usual termination of cases of tumour and cerebral abscess, as of the vascular lesions described in the last chapter, is by stupor, which gradually passes into *coma*. Sometimes the patient lies for weeks without taking the slightest notice, passing all his evacuations under him, and showing no sign of intelligence, except that he slowly swallows the food that is put into his mouth. Some years ago Sir William Gull had under his care a boy

* These cases seem to have an important bearing upon the general theory of the production of "cerebral symptoms" by local affections of the brain. I shall hereafter have to describe a group of functional disorders of the nervous centres, including migraine, vertigo, epilepsy, and some others—under the name of "nerve-storms" or "explosive neuroses." And I shall endeavour to show that each of these is liable to be set up by a variety of exciting causes. Now, my hypothesis is that a tumour or a tubercle causes a transitory vertigo, or an epileptiform fit, or an attack of sick-headache in exactly the same way as any other disturbing agent. I conceive that the nerve-storm so produced has precisely the same seat as when it is merely the result of over-fatigue, or irritation of the generative organs, or disorder of the stomach. And I think it is probable that frontal headache, even when unattended with the other characteristic symptoms of an attack of migraine, is yet very often of that nature. If this be granted, it ought to follow that pain in the forehead should point less directly to the anterior part of the brain as the seat of a tumour than occipital pain to the cerebellum or posterior lobes.—C. H. F.

who manifested a remarkable retardation of intelligence. If a question was put to him he seemed not to heed it; but after many seconds, when the questioner had passed on to talk to someone else, he would deliver, word by word, a reply which showed that he perfectly understood what had been said. In other cases the mental condition undergoes changes which may perhaps depend on varying degrees of pressure by ventricular effusion. After lying in a stupor for two or three weeks the patient may recover his senses, remain conscious for several days, and then relapse into his former state.

2. *Vomiting* is a frequent and most important symptom—commonest perhaps with cerebellar tumours. The bowels are usually constipated as in other chronic cerebral diseases, and the abdomen is often hollow, the walls retracted, and the intestines empty. As a rule, there is loss of flesh, and extreme emaciation sometimes occurs. But a boy of fourteen, who was in Guy's Hospital in 1867, became remarkably fat during his illness, and remained so until he died; and two or three years previously the body of a young woman in a similar condition was brought down into the *post-mortem* room. In each case there was a tumour at the base, growing upwards into the third ventricle.

The *temperature* of the body is often one or two degrees below normal; but before death fever may develop itself. Obernier speaks of a rapidly advancing case in which every exacerbation of the headache was associated with a marked fall in the rate of the *pulse*. The mode of death is often by cessation of *breathing*, the heart continuing to beat for some little time; in one instance it went on for thirty-five minutes, while artificial respiration was vigorously kept up. In such cases it is wonderful how quietly life departs, without a gasp or a moan, or the movement of a limb.*

3. *Changes in the optic disc and retina.*—In 1860 von Graefe communicated to the German 'Archiv für Ophthalmologie' a short paper, in which he stated that inflammation of the optic nerves within the eyes sometimes occurred as a complication of cerebral diseases. It was already known that *blindness* was a frequent effect of tumours of the brain, even when their seat was not such as to involve any of those parts which were supposed to be functionally related to the sense of vision, but the belief had been that paralysis of the nerves of sight was the cause of the amaurosis, and that if any anatomical change was to be found it would be a simple atrophy from disuse. Thus von Graefe confesses the surprise that he felt when he first discovered (about the year 1857) that the optic discs were swollen and reddened in a case of this kind. His observations were soon confirmed by others, and after a while the remarkable fact was elicited that precisely similar appearances could often be detected when the patient was not conscious of any visual defect. Thus the ophthalmoscope has acquired great value in the diagnosis of diseases of the brain.

It was suggested by von Graefe himself, in his earliest communication, that there were two separate ways in which changes in the discs could arise, and that these were characterised by different appearances. On the one

* Some years ago I was called to see a female patient, whose symptoms pointed to the presence of a cerebral tumour, with Dr. Blades, of Kennington. On my arrival at the house he came out of her room to speak to me, leaving her husband and two women with her. When we went to her bedside a few minutes later we found her dead, except that a slight flickering of the pulse was still perceptible. Not the slightest change had been observed.—C. H. F.

hand, an increase of intra-cranial pressure, acting upon the cavernous sinuses, might mechanically obstruct the return of blood through the retinal veins; on the other hand, an inflammatory process at the base of the brain might be propagated as a "neuritis descendens" along the optic nerves to their terminations within the eyeball. Subsequent writers have to some extent modified the interpretation of these two conditions, and it has been shown that they very often co-exist. The one is known to the Germans as the "Stauungs-papille;" following Dr Allbutt, English writers term it the "Choked Disc," or (with less propriety) "Ischæmia of the Disc." The other is called "Optic Neuritis," "Papillitis," or "Neuro-retinitis descendens." There is also a third change, "Atrophy of the Disc," which may either arise independently or be consecutive to neuritis.

The choked disc.—There is no better description of this affection than that which von Graefe gave in his account of the first case that came under his observation. "The papilla," he says, "was greatly and irregularly swollen, rising steeply on one side and falling gradually on the opposite side to the level of the retina. . . . . Instead of being transparent its tissue looked grey and opaque, with an extremely deep reddish tint, and the adjacent part of the retina had the same appearance, so that the choroidal margin was completely hidden. The opacity was diffused, except that with the direct method of examination one could perceive a striated appearance following the course of the fibres of the optic nerve. The retinal veins were dilated, exceedingly tortuous, and obscured here and there by dipping into the opaque tissue; the arteries were comparatively small. The turbidity of the retina diminished gradually from the disc outwards over a zone of rather more than 2 mm. in breadth, so that it occupied an area 5 mm. in diameter (including the disc itself)." In a second case there were ecchymoses in the part of the retina near the disc.

The prominence formed by the optic disc in a case of this kind appears to be easily recognised after death when the eye is removed and laid open; an excellent illustration of it is given by Dr Allbutt. In one instance in which an intercurrent attack of smallpox destroyed life at an early stage of the ocular affection, Cornil found that the microscopical appearances consisted in an infiltration of the connective tissue with serum, and in a few hæmorrhages into the adjacent part of the retina ('Arch. Gén.,' 1868, ii, p. 679). The absence of grave morbid changes is proved by a case of Mr Lawson's, in which the presence of a hydatid cyst within the orbit caused an extreme state of "choked disc;" four days after puncture of the tumour the engorgement had almost entirely disappeared. A drawing in 'Pagenstecher's Atlas' (Pl. xxxi, fig. 7) shows the nerve-fibres bulging outwards, so as to separate the peripheral layers of the retina from the choroid. In some more advanced cases of von Graefe's, examined by Schweigger and Virchow, the connective-tissue elements, the vessels, and the nerve-fibres were all found swollen, and the latter were beginning to degenerate, while in the outer coat of the vessels there was an overgrowth of nuclei.

The choked disc was attributed by von Graefe to compression of the cavernous sinus, aided by what he termed the constricting action of the sclerotic ring. He argued that if from any cause the flow of blood along the retinal veins was obstructed, the unyielding structure would give rise to a sort of *strangulation* of them at the point where they pass through it, and so he explained the fact that the congestion was limited to the intra-ocular termination of the optic nerve; but (as Dr Hermann Schmidt has

urged in vol. xv of the 'Arch. f. Ophth.') the ophthalmic vein communicates so freely with the facial vein that it is difficult to see how pressure upon the cavernous sinus could appreciably interfere with the escape of blood from the eyeball, nor does it appear probable that the wall of the sinus would yield to any moderate force. These considerations are confirmed by a case under the author's observation, in which the sinus on one side was completely obstructed by softening thrombus; the corresponding optic disc had been noticed during life to be perfectly normal. In all probability Schmidt's explanation is the correct one. He finds experimentally that an injection of Prussian blue into the arachnoid cavity (subdural space of the brain) makes its way through the optic foramen into the space between the two sheaths of the optic nerve, and fills a fine network of lymphatic channels within the lamina cribrosa (formed by the sclerotic ring) between the very fibres of the nerves themselves. He therefore suggests that some of the fluid which is always present in small quantity in the arachnoid cavity is driven into the optic nerve in a similar manner whenever the intra-cranial pressure is from any cause increased. As a matter of fact, a watery liquid has more than once been found distending the sheath and giving it a bulbous appearance, and this liquid readily escapes as soon as a puncture is made. One difficulty is in explaining on Schmidt's theory why cerebral hæmorrhage does not cause choked discs. Is it because the great force suddenly exerted flattens the sheath of the nerve, and closes the channel through it?

Optic neuritis.—The distinctive features of this affection, as compared with choking of the disc, are that its swelling and redness are less marked, but that it looks more opaque, and that the morbid process extends further into the retina itself, and (according to von Graefe) involves its middle and outer layers, as well as its inner layer. Dr Allbutt endeavours to describe the appearance of the disc by saying that there is not "a circumscribed intense redness, or brownish grey, but rather a wash of reddish lilac or a grey tint." And he adds that one does not perceive "a multitude of minute branches and capillaries," such as give a "mossy" look to the choked disc, but that the vessels which become distended and tortuous are rather the main trunks. Moreover, these are often completely concealed in part of their course by the opaque tissue, beneath which they dip.

One of the chief microscopical appearances seems to be that the optic nerve-fibres within the disc are enlarged and beaded, presenting a series of fusiform swellings. The connective-tissue bundles are said by Virchow to present no excess of cells or nuclei, but the coats of the vessels are thickened. The trunk of the nerve in its whole length shows an accumulation of cells and nuclei within its sheath, and also between its fasciculi.

As stated above, von Graefe ascribed neuro-retinitis to the direct extension of inflammation downwards; as, for instance, from a basal meningitis. We shall find that this explanation is not always applicable. The probability is that the affection is then secondary to a choked disc, being developed in the same way as those chronic affections which are well known to occur in the lungs and liver and kidneys when there is obstructive disease of the heart. It is not surprising that (as Mr Hulke has remarked) mixed forms of ophthalmoscopic changes are more commonly seen than typical specimens of a "Stauungs-papille" or of neuro-retinitis.

Dr Gowers holds that congestion of the disc is not the result of intra-cranial pressure, that it is always inflammatory or irritative in origin, and

that the distinction between the choked disc and optic neuritis is one of degree only.

Atrophy of the disc.—Neither congestion of the disc nor neuro-retinitis is a permanent affection. They are not even stationary; for the process, if the patient lives long enough, must subside or quickly end in atrophy. The latter is by far the most common termination. The disc becomes less and less swollen, and at length is quite flat, or even sinks below the level of the surrounding retina. Its red and grey tints grow into a dirty white colour. The tortuous veins diminish in size; spots of hæmorrhage fade and are absorbed. The outline of the disc remains for some time blurred and irregular, its margins are ragged, and streaks of exudation are to be seen in the course of the retinal vessels. This description of "consecutive atrophy" is taken from Dr Allbutt, but it accords with those given by all other writers. He goes on, however, to say that these appearances also are transitory. Little by little the disc clears up; its edge becomes sharply defined; its surface dead white and glistening. Its condition is then undistinguishable from one which has been preceded by no swelling or inflammation of the disc—the "simple white atrophy" of writers. Pagenstecher, indeed, stated that in microscopical sections of the dead tissues the origin of the affection may be recognised by the permanent displacement outwards of the two external layers of the retina from their normal commencement close to the edge of the choroidal ring. As to the histological changes in the disc itself, he shows that all the nervous elements may disappear, and be replaced by coarse connective tissue.

It is surprising how little impairment of vision attends these changes in the optic discs in many cases. Pain and over-sensitiveness to light are constantly absent. If there is any affection of sight, it is that the patient either cannot see at all, or sees objects more or less indistinctly, as if through a mist. Dr Allbutt speaks of several patients with choked discs who could read a badly printed news-sheet with ease. One should therefore make it a rule to examine with the ophthalmoscope all cases in which symptoms of cerebral disorder are present; unless, indeed, an exception may be made for some of the simple uncomplicated neuroses. On the other hand, if a patient is found to present morbid appearances in the fundus of the eye, one should not be contented with his statement that his sight is perfect. The extent of the visual field in all directions should be accurately explored; and perhaps it may turn out that although vision is good at the centre, it is yet very defective at the periphery or towards one side. When blindness sets in, it sometimes seems to come on almost suddenly, although the changes in the discs were no doubt developed very gradually. This occurred, for instance, in a patient under my care in 1878; about three weeks before her admission she went to sleep one afternoon, and on waking up found that she was totally blind. If perception of light is completely lost, the irides are widely dilated and motionless. But in those cases in which the impairment of sight is partial, the pupils often appear to be of normal size, and their movements are sometimes not even sluggish. The suggestion of M. Jaccoud, that the excitation of reflex contraction of the iris by light is a proof that blindness is due not to any affection of the optic nerve within the eye itself, but to a lesion situated above the corpora geniculata, seems to be altogether fallacious.

When a choked disc, or one affected with neuritis, passes into a state of atrophy, the patient's sight often becomes progressively worse; but some-

times, on the other hand, it shows a marked improvement. Thus a patient of Dr Goodhart's, who at one time could see absolutely nothing with her right eye, was ultimately able to read Snellen's $2\frac{1}{2}$, though with difficulty, at a distance of about a foot. When the power of vision has been but slightly impaired during the early stage of the disease, it is sometimes perfectly regained; but even in such cases, if actual neuritis has been present, the disc seems invariably to become more or less atrophied; it never resumes its normal appearance.

Localisation of organic cerebral lesions.—We now turn to other symptoms, which not only indicate in general the *presence* of some local lesion—whether a tubercle, gumma, or tumour,—but also point more or less definitely towards its exact *seat;* they constitute what Dr Jackson terms "localising symptoms."

In the interpretation of these symptoms there is this preliminary difficulty. When one finds a tumour, or a tubercle, in some particular region of the brain, one cannot tell whether the disturbances of function to which it gave rise were the results of *irritation* of the structures around it, or of *destruction* of those among which it grew. In the latter case the symptoms would be those of the uncontrolled or unbalanced action of the corresponding parts on the opposite side of the brain, or of some other parts physiologically antagonistic to those containing the lesion. It is precisely this difficulty which makes it impossible to attach an exact meaning to inequality of the pupils; and several other instances will present themselves further on. Dr Jackson distinguishes cerebral lesions as "destroying" or "discharging." It is remarkable how great a size may be reached by a mass in the brain, without its depriving the structures in which it is embedded of their function; while, again, a tumour sometimes compresses adjacent parts, so as to annihilate their activity. Without attempting to lay down a positive rule, it may be said that, for the diseases now under consideration, the presumption is in favour of irritation, rather than destruction, when either explanation is admissible.

The base.—Beginning at the base of the brain, and passing from before backwards, one meets with the simplest of all localising symptoms, namely, those which depend on interference with the various cranial nerves.

It is easy to see that complete *anosmia* points to the presence of disease near the ethmoid bone, or involving the inner and lower parts of the two anterior lobes; while loss of smell on one side may be due to a lesion implicating one olfactory bulb, or the root of the nerve extending outwards to the Sylvian fissure.

A growth pressing upon the optic chiasma produces various effects according to its exact situation. Thus there may be more or less complete loss of sight in one eye, or even total blindness; but as changes in the discs are almost certain to be present, it would be scarcely possible to draw any inference from this symptom. What is really significant is the limitation of a visual defect to half the field in each eye, or *hemiopia* (cf. p. 567). Of this there are three different forms, but their interpretation is still somewhat doubtful, because opposite views are held as regards the structure of the chiasma. On the theory of semi-decussation, which appears the more probable, they may be described as follows:

(1) Compression of the centre of the chiasma, cutting off the decussating inner fibres of each optic nerve, will cause loss of vision over the temporal

field in each eye (*double temporal hemiopia*); (2) compression of one optic tract will deprive the patient of the nasal field in the corresponding eye, and of the temporal field in the opposite eye (*homologous lateral hemiopia*); (3) loss of vision in the nasal fields of the two eyes (*double nasal hemiopia*) can only be due to a double lesion, symmetrically placed so as to interfere with the non-decussating outer fibres on each side. Examples of all these forms of hemiopia are known to occur. Homologous lateral hemiopia is very common in attacks of migraine; of double temporal hemiopia cases have been recorded by Sämisch and by E. Müller, in each of which a large tumour lay in the middle line, involving the chiasma, and a third very singular one by Dr Weir Mitchell due to pressure of an aneurysm of an abnormal anterior communicating artery ('Journ. Nerv. and Mental Dis.,' Jan., 1889); of double nasal hemiopia, one by Knapp, in which the pressure at the necessary points was effected by dilated and atheromatous branches of the circle of Willis.*

Intra-cranial growths sometimes produce *deafness* when they occupy, or extend into, the space between the internal auditory meatus and the side of the pons. Dr Hughlings Jackson has met with one case in which there was loss of hearing from this cause without any facial paralysis. In another instance a complete bilateral destruction of the auditory sense was imperfectly explained by the autopsy, for the only growth at the base was one of the size of a hazel-nut on the *left* side. It might be suggested that this symptom ought sometimes to be referable to an affection of the brain itself; but Dr Jackson's experience appears to negative such an opinion.

With regard to affections of the other cranial nerves, there is little to add to the remarks made when describing their symptoms (see pp. 407—420). An anatomist can sometimes infer the seat of a growth with great accuracy from the implication of some nerves while others escape. Thus, in one instance, the fact that all the muscles of the eyeball were paralysed, while no part of the fifth nerve was interfered with except its ophthalmic branch, seemed to prove that the disease occupied the sphenoidal fissure. On the other hand, it is sometimes possible to draw the conclusion that no single lesion will explain every feature of the case, a conclusion which (as we shall presently see) may be of considerable diagnostic importance. Paralysis of the third nerve, if due to an intra-cranial tumour, points particularly to a syphilitic gumma of the base.

The cerebellum.—The localisation of a tumour or tubercle in the cerebellum is often attempted, and is not infrequently successful. But one must not forget that this part of the encephalon is a very common seat of such growths, so that the result of the diagnosis may possibly sometimes be due to good luck rather than to skill. Beside occipital headache, contraction of the muscles at the back of the neck, vomiting, convulsions, blindness, and vertigo—no one of which symptoms is special to lesions of the cerebellum—there are some others which are believed to be more characteristic; particularly a *reeling, staggering gait*, like that of a drunken person, but with a tendency to fall in some particular direction. It was long

* On the theory of complete decussation, "double temporal hemiopia" would be caused only by pressure on the *front* of the chiasma, while pressure on the *back* of the chiasma by a single growth would account for "double nasal hemiopia." So far that theory might hold, although both these kinds of hemiopia are very rare, but it gives no explanation of the far more common "homologous lateral hemiopia," excepting the untenable one of a lesion being placed *on one side* of the chiasma, in such a situation as to compress a part of the optic nerve, and also a part of the optic tract on that side.

ago shown by the experiments of Flourens on pigeons that excision of the cerebellum rendered the bird unable to walk or to fly, or to perform regular determinate movements; and he suggested that the function of the organ was one of co-ordination. Subsequent investigations have proved that a large part of the process by which the actions of the individual muscles are harmonised and combined takes place in the spinal cord. But this fact does not exclude the possibility that a higher co-ordination may be effected by the cerebellum; and an hypothesis has been suggested by Dr Broadbent, namely, that what it does is to bring muscular action into relation with visual impressions, as when movements have to be guided by sight; whereas in the spinal cord they are arranged for tactile and other cutaneous impressions. However, a patient suffering from disease of the cerebellum may still stagger, although, in consequence of his optic discs having undergone atrophy, he can no longer see anything.

When the staggering is accompanied by a tendency to fall in one particular direction, we might expect that this circumstance would not only indicate the presence of disease in one side of the cerebellum, but also show which side is affected. But tumours of the cerebellum often attain a great size, and destroy a large part of the organ, beside compressing other parts or interfering with their supply of blood. Moreover, the same affection may produce diametrically opposite effects, according as its action is that of a "destroying" or of a "discharging" lesion.

In 1877 an autopsy in a case of Dr Frederick Taylor's showed a cheesy tubercle in the cerebellum, rather to the right of its centre; the right lateral lobe was universally pale and softened, and full of granule-masses. The patient was a boy, five years old. It so happened that the exact seat of the mischief had been indicated several months before his death, by a bulging of the right side of the occipital bone, which was so much thinned at one spot that it would yield on pressure, and rebound like a piece of tin or cardboard. At the same time it was noticed that when he sat up in bed he had no balancing power; but he did not roll over on one side rather than on the other. The eyes were affected with a peculiar form of nystagmus, which might perhaps have been turned to account as a localising symptom. "It came on only when he lay on the left side; the eyes would then gradually fall over to the left, and be suddenly jerked back to the right; and these movements would be repeated rhythmically. When he sat up in bed there was a continuous rhythmical movement of the head from left to right." Afterwards, six weeks before he died, "he lay on his back, with his head turned to the left; his eyes were then directed to the left side, and jerked from time to time upwards." Now, Hitzig, following Purkinjé, has shown ('Reichert's Archiv,' 1871) that by passing a galvanic current through the head of a healthy person, from one mastoid process to the other, one can obtain oscillatory movements of the eyes exactly like those observed in Dr Taylor's patient; and in a subsequent paper he accounted for those effects by referring them to disturbances of the cerebellum. Dr Ferrier, too, found that galvanising the exposed cerebellum of monkeys and other animals caused the eyes to deviate in different ways, according as the poles were applied to different regions of its surface. Indeed, his experiments seem to indicate a very simple law of localisation, namely, that when any part of the cerebellum is the seat of irritation the eyes become turned in the corresponding direction, whether to the right or to the left, upwards or downwards, as the case may be. In many cases analogous movements of the head accompanied

those of the eyes. Thus a tendency to fall backwards, which has sometimes been noticed in cases of cerebellar disease, would point to the upper surface of the organ as its seat; for Dr Ferrier found that galvanising that part in monkeys led to upward movements of the eyes, and to throwing back of the head. Dr Taylor's patient had also left hemiplegia, which was no doubt due to compression of the right side of the pons by the tumour.

Hemiplegia in cerebellar disease appears to be always produced in that way, and it is usually "crossed," affecting the limbs on the opposite side to the cerebellar lesion. But the functional relations of each half of the cerebellum are nevertheless chiefly with the limbs of the same side of the body through the connections of the fibres of the middle peduncle with nuclei in the opposite half of the mesencephalon. This is proved, not only by anatomical and physiological investigations, but also, and still more convincingly, by the pathological fact that when there is congenital unilateral atrophy, affecting one hemisphere of the brain, one crus cerebri, and one side of the deep part of the pons, the wasting is found in the opposite side of the cerebellum, as it is in the opposite side of the spinal cord.

On the whole, it may be said that when there are the general symptoms of an intra-cranial tumour (including tubercle, gumma, cyst, and abscess), namely, headache, vomiting, and optic neuritis, especially optic atrophy and amaurosis—and when there is no hemiplegia, but only general muscular weakness, when there is spasm of the muscles at the nape of the neck, and decided vertigo and loss of power to maintain equilibrium—the diagnosis of the cerebellum as the seat of the lesion is almost certain.

This last symptom, disturbance of equilibrium, is said by Nothnagel to depend on lesion of the superior vermiform process, and this conclusion is confirmed by other observers. Tumours of the lateral lobes of the cerebellum appear to have no special symptoms; but they may sometimes be more than guessed at by the effects they produce through pressure on the pons or other adjacent structures.

The motor area.—Passing now to the regional diagnosis of lesions involving the motor tract, we may observe that the greater part of the description of hemiplegia given in the last chapter applies to the same symptom when it is produced by a new growth. But whereas we have seen that certain parts of the brain are far more liable than others to suffer from the effects of embolism, or of rupture of a cerebral artery, the distribution of tumours is comparatively irregular and capricious. They may interfere with the fibres which pass down to the spinal cord at any point in their course, and may destroy them either in whole or in part. On the other hand, it is wonderful how large a tumour may be found in the very substance of the motor tract, without completely abolishing its functions. In 1869, a boy, aged four years and a half, died in Guy's Hospital under the author's care, after an illness of fourteen months' duration. Three months before his death he could sit up in bed, although he rolled about and his balance was easily upset. A month later he "could move his legs a very little." Dr Moxon found that the pons was occupied by an immense caseous tubercular mass, which consisted of two halves fused together, and preserving almost exactly the normal shape of the part; only a thin shell of nervous matter remained. It seemed marvellous that life could have been maintained while the mass was growing to such a size. In another case a minute tumour was found in one of the corpora dentata of the bulb, which had given rise to no symptoms of disease of that part.

Then, again, paralysis of the limbs on one side of the body, or even of all four limbs, may be due to a mass pressing on the motor tract from without; for instance, to a sarcoma connected with the base of the skull, and compressing the medulla oblongata or the pons; or to a glioma in the hemisphere above the lateral ventricle, pushing downwards and flattening the basal ganglia. In other cases, when the tumour lies altogether outside the motor region, hemiplegia is caused by the yellow softening that so often develops itself secondarily.

A growth situated in the superficial convolutions of one *hemisphere* may affect the movements of the opposite side of the body, without either disturbing the corpus striatum mechanically by pressure, or involving it in any morbid action. The symptoms so produced are among the most interesting that come under the observation of physicians. They are generally convulsive in character, but the spasms are often followed by a transitory paralysis; and it is still a question whether a loss of power may not occur primarily and alone. Bright was the first to point out, in the earliest volume of the 'Guy's Hospital Reports' (1836), that some cases in which fits were due to a local lesion presented the peculiarity that consciousness was not lost. But this form of convulsions was never systematically investigated until, about 1865, Dr Hughlings Jackson took up its study, in the hope that it would throw important light upon the nature and seat of epilepsy in general. He insisted on the fact that *hemispasm*—the "mobile counterpart" of hemiplegia—must indicate a condition of "instability" in the convolutions which discharge through the corpus striatum, and must therefore be a symptom of disease in those convolutions or (possibly) in the corpus striatum itself. And he set to work to determine, so far as pathological opportunities might offer themselves, the exact seat of the lesions found where this symptom had been present. His theories have since received remarkable confirmation by direct experiment, and the particular form of convulsions in question is now commonly known abroad as "Jacksonian Epilepsy."

It was in 1870 that Fritsch and Hitzig made known the fact that, instead of the surface of the brain being insensible to galvanic currents, as Schiff and other physiologists stated, there were in the dog certain parts of the convolutions which reacted to such currents in a very definite way, each setting in motion some particular limb, or even some special set of muscles. Thus they laid down the position of "cortical centres" for the movements of the neck, face, fore- and hind-leg respectively. Three years later Dr Ferrier repeated these experiments with the faradic current, employing various animals, and at length monkeys, in which the principal convolutions are comparable, one by one, with those of the brain of man. Afterwards Hitzig himself operated on a monkey. Between the results of these two observers there were some discrepancies in details. Hitzig used a comparatively weak galvanic current; thus he obtained movements over a far more limited area; indeed, his main object was to discover what parts of the cortex would yield movements limited to isolated groups of muscles on the most feeble stimulation. He maintains that in the monkey the motor centres for all parts of the body are situated in the anterior central (ascending frontal) convolution. That for the leg is nearest the falx cerebri, at a distance of about three millimetres from it; that for the arm lies three millimetres further outwards; that for the upper part of the face, supplying the muscles of the ear and eye, is situated rather more

behind and externally; that for the lips, tongue, and jaws is six millimetres inwards from the fissure of Sylvius. Hitzig did not deny that irritation of adjacent convolutions by more powerful (especially by induced) currents gives rise to movements in distant parts; but he attributed them to the action of the current upon parts beneath the cortex.

Ferrier placed his motor centres in the posterior central (ascending parietal) as well as in the anterior central (ascending frontal) convolution, and also in the postero-parietal lobule; and his sensory centres in the back part of the third frontal (speech), in the angular (vision)* and in the superior temporo-sphenoidal convolution (hearing). He agreed with Hitzig in placing the centre for the leg close to the median line, but he divided it into two,—one in the postero-parietal lobule, for advance of the hind limb, as in walking; the other in the upper parts of the ascending parietal and ascending frontal convolutions, for climbing and other complex movements of arms and legs. He made the centres for the arm and hand occupy the ascending parietal convolution nearly as far outwards as the fissure of Sylvius, as well as the ascending frontal and the superior frontal convolutions outside and in front of the leg-centres. The movements of the lips, tongue, and mouth he connected with a series of centres occupying the lower part of the ascending frontal, and with one in the supra-marginal convolution. Centres for the movements of the eyes were believed to occupy an extensive area in the two upper ("first" and "second") frontal convolutions. Stimulation of the angular gyrus, or of the superior temporo-sphenoidal convolutions, also caused the eyeballs to move, with dilatation of the pupils; but he supposed these parts to be centres for the senses of sight and hearing, and the movements to be reflex.

Since the publication of Ferrier's book in 1876, Nothnagel, Munk, Goltz, and other experimenters in Germany, and Burdon-Sanderson, Yeo, Schäfer, and Horsley in England, have repeated and varied his experiments. The stimulation of definite cortical areas has been controlled by destroying corresponding parts of the hemispheres. At the International Medical Congress which met in London in 1881, Prof. Goltz brought a dog from Strasburg which had survived extensive destruction of successive portions of the cerebral cortex, and this living witness was confronted by a monkey which was brought forward by Dr Ferrier. After observation of the functions of both animals they were destroyed, and the brains were subsequently submitted to most exact and thorough anatomical examination by Dr Klein, Mr Langley, Mr Schäfer, and Dr Gowers. The account of the discussion in the 'Transactions' of the Congress (vol. i, pp. 218—240), and the detailed reports by Langley and by Schäfer, published in the 'Journal of Physiology' (vol. iv, pp. 248—326), furnish an admirable example of the difficulty of ascertaining and interpreting scientific facts, and of success in at least the former task.

The practical difficulties have been—in faradic stimulation, the danger of a current spreading, either too widely or too deeply; in destructive operations, the appearance of much wider and more complete ablation than proved to be the case; in pathological observations, the infrequency of locally circumscribed, single and uncomplicated lesions; and, generally, the fallacies resulting from vaso-motor disturbance, from inhibition of distant ganglionic centres, and from direct or indirect mechanical pressure.

* In the second edition of Dr Ferrier's work, 'The Functions of the Brain,' 1886, he includes the occipital lobes in the visual area (pp. 271 *et seq.*).

Nevertheless, pathological cases completely observed, completely examined after death, and free from complications, have gradually accumulated. A new series of experiments on the monkey's brain has been carried out by Profs. Ferrier and Yeo, and an independent series, with no less skill and care, by Profs. Schäfer and Horsley. In the congress of physiologists which met at Bâle in September, 1889, Mr Horsley and Dr Beevor demonstrated on a monkey under anæsthetics the accuracy with which predicted movements of the thumb, forearm and shoulder, the eyes and the tongue could be produced by faradic stimulation of definite areas of the cortex.

It may now be taken as certain that there are excitable areas in the neighbourhood of the fissure of Rolando, which are connected with definite movements. The exact locality of the motor areas has been accurately ascertained, and has been confirmed by the crucial proof of operation upon human patients. Other portions of the cerebral cortex are not thus excitable. The precise localisation of sensory areas is still doubtful. Disregarding, therefore, the anterior frontal, the posterior parietal, occipital, and temporo-sphenoidal regions of the cortex, we have a "motor area" around the fissure of Rolando, which includes the ascending frontal with the closely adjacent part of the third, second, and first frontal convolutions, and the ascending parietal, together with the inner aspect of the same, which forms part of the marginal gyrus, and the front of the superior parietal lobule (postero-parietal of Huxley and Turner). Irritation of these parts is capable of causing definitely distributed clonic spasms of the muscles on the opposite side of the body—a "discharging" lesion; destruction of the same parts is capable of causing definitely distributed loss of power in the same muscles on the opposite side of the body—a "destroying" lesion.

The area which corresponds with certain movements of the *leg* comes first, occupying the borders of the fissure of Rolando close to the falx cerebri, and extending over the adjacent parts of the ascending frontal (or præ-central), the ascending parietal (or post-central), and the inner surface of the same part of the hemisphere, which corresponds to the marginal convolutions immediately behind the calloso-marginal fissure. The area which corresponds with movements of the *arm* is below and external to the last, and occupies the ascending frontal and parietal convolutions opposite the second frontal gyrus in front and the angular gyrus behind. The area which corresponds with movements of the *facial muscles* appears to be lower down in the same direction, in front and behind the lowest point to which the fissure of Rolando reaches. Lower still, at the angle between the ascending and horizontal branches of the Sylvian fissure, opposite the third frontal convolution, this region marches with the gyri operti, the insula, and Broca's aphasic region.

Lastly, high up and internal is a motor area which lies in front of that for the lower extremity, occupying the back part of the first frontal convolution, which is believed to be associated with movements of the trunk on the opposite side.*

* Centres for the muscles of the eyeballs, for movements of the tongue and jaw, and for movements of the tail, have been ascertained with more or less exactitude in the monkey and the dog. The difficulty of comparing the results, even in the former animal, with its different mode of progression and of prehension from human physiology, is obvious, and is fully recognised by Ferrier. Disturbance of the ocular muscles in man appears to be more often connected with lesions of the motor nerves, of the bulb or of the cerebellum, than with those which affect the cerebral cortex.

When we apply the knowledge thus obtained with a view to the diagnosis of circumscribed lesions of the cerebral cortex, we are met by certain clinical difficulties.

In the first place, it is to be noted that the occurrence of convulsive attacks without unconsciousness beginning in, or limited to, some particular part of the body, is not of itself a proof that a recognisable local lesion exists in the brain at all. We shall find several instances of epilepsy in which attacks of the kind were almost certainly "functional." Thus in a case of Dr Jackson's, the only morbid change discovered at the autopsy was atrophy of both hemispheres, although the fits which had occurred had begun in the right index finger and thumb, and had often been unattended with loss of consciousness ('Med. Times and Gazette,' 1872).

Moreover, according to Dr Jackson, the seat of localised convulsive seizures, or of general seizures beginning with local spasms, is in the majority of cases some part of the hand, generally the thumb or the forefinger; the next most frequent seat is the cheek or the tongue, and it is much more rarely the great toe.

The results of experiment have, however, been confirmed by clinical experience. Some of the earlier cases may be briefly cited. (1 and 2) Two cases of Jackson's (one recorded in the 'Med. Times and Gaz.' for 1872, the other quoted by Ferrier), in each of which the spasms always began in one thumb, and a lesion was found in the opposite first frontal convolution. (3) A case at Guy's Hospital where we found in the back part of the first frontal gyrus a small glioma on the right side; there had been repeated fits without unconsciousness, starting mostly in the left foot, but occasionally in the left arm. (4) A patient of Griesinger's, who was attacked with transient spasms in the right leg, afterwards affecting the right arm, the face, and the tongue; a cysticercus lay close to the left side of the falx cerebri, in such a position that its anterior extremity coincided with a line drawn vertically upwards from the ear. (5) Recorded by Dr Dreschfeld, of Manchester ('Lancet,' 1877). The convulsive movements began with a sudden clenching of the left fist, flexion of the wrist, and pronation of the forearm, while the left angle of the mouth was at the same time strongly drawn downwards; a local syphilitic lesion was found in the adjacent parts of the ascending parietal and supra-marginal convolutions. (6) A case observed by Hitzig. The patient was a French soldier who was wounded on the right side of the head near Orleans on December 14th, 1870. On February 4th, 1871, he was attacked with clonic spasms affecting the left side of the mouth and nose, the eyelids, and afterwards the fingers on that side. After death there was found to be a local necrosis of the parietal bone, and an abscess in the right ascending frontal convolution. (7) Another instance, very similar, has been recorded by Wernher ('Virchow's Archiv,' lvi, p. 289). The patient, who had fallen from a railway truck, was attacked with convulsions limited to certain muscles on the right side, especially those of the angle of the mouth, the ala nasi, the eyelids, and the tongue; after death the left temporal bone was found fractured, and the surface of the brain crushed on each side of the Sylvian fissure at the lower end of the fissure of Rolando. (8) A case of Dr Gowers ('Brit. Med. Journ.,' 1874) in which spasms began in the left angle of the mouth, involving afterwards the frontal muscle on each side, but in which the only local lesion appeared to be a clot of blood situated above the right lateral ventricle, just inside the gyrus fornicatus. This case certainly does

not correspond with the observations of Hitzig and Ferrier; but it does not contradict them, as if, for example, a small tumour were to be found in the occipital lobe when limited spasms had been present during life.* (9) A case reported by Ferrier ('Brain,' April, 1880) of convulsions in the left arm and leg following hemiplegia, in a man the subject of phthisis. At the autopsy a tubercular growth was found occupying both sides of the fissure of Rolando on the external aspect of the right hemisphere, and extending into the internal aspect as well.

During the last ten years many similar cases have been recorded by Jackson, Gowers, Bastian, Hadden, and other observers in this country; and a still larger number in France, Germany, and America.

We are now justified in stating that lesions of certain particular convolutions are capable of causing limited paralysis instead of spasms. Dr Hughlings Jackson long ago pointed out that unilateral convulsive seizures were often followed by a more or less complete hemiplegia; but he then believed that this form of paralysis was always transitory, passing off in a few days or weeks. No doubt persistent local paralysis is seldom or never caused by a cerebral tumour, unless it interferes directly with the corpus striatum, or with some part of the motor tract. But Dr Jackson's distinction between "discharging" and "destroying" lesions is in harmony with the fact that although paralysis may not be produced by a new growth in a convolution, it may yet result from softening in the motor region; and almost every instance of aphasia is a case in point. Hence the most careful scrutiny of the convolutions near the fissure of Rolando should be made whenever a patient has had unilateral ptosis, or paralysis confined to part of the face, or to a finger, or any part of the upper limb on one side. The results of Ferrier's and subsequent experiments are decisive of the physiological fact, and clinical observations to the same effect are recorded; two early ones by Löffler were quoted by Hitzig. One is the case of a man whose two parietal bones were both fractured at the vertex by a gunshot wound; he had paralysis of both legs. Another is that of a man who was wounded at the upper and anterior angle of the left parietal bone; his right leg instantly became paralysed, and he fell to the ground. On the seventh day the loss of power extended to the right arm also, but this quickly got better, while in the leg the recovery was very slow. Judging from experiments on dogs and monkeys, paralysis caused by a cortical lesion ought to be limited to some special movements of the affected

* There is, however, a case of Sir William Gull's in which a large abscess in one posterior lobe was attended with attacks of spasm limited to one arm; and a few other cases have been recorded which would appear inconsistent with the experimental results given above, were it not that legitimate criticism seems to deprive them of decided significance. One of these was observed by Dr Jackson. The foot had been the starting-point of the spasms, and a tumour was found which involved the lower part of the ascending frontal convolution; but the brain also presented other lesions. Another is a case of Dr Gowers', in which there was thrombosis of the superior longitudinal sinus and of some of its afferent veins, with hyperæmia of parts of the three frontal convolutions, situated further forwards than any recognised "cortical motor centres;" but in that instance the fits were general, although they began with a slow movement of the hand to the head; and death occurred within two hours from the time of their commencement. Again, in a patient of Dr Buzzard's, a girl of eighteen, a tumour of the size of a walnut was found in the white substance of the *left* hemisphere, extending as far as the grey matter of the gyrus fornicatus; the cause of death was phthisis. The symptom which had suggested the idea that a local lesion might be found was that she had fits beginning with an aura in the *left* wrist; but this is quite a different thing from the occurrence of spasm in the same part. Moreover, the application of a blister to the seat of the aura sufficed to transfer it to the opposite arm.

muscles. An instance of this is afforded by Hitzig's case of the French soldier referred to above (No. 6). His spasms were followed by a partial paralysis of the lower part of the face on the left side; and it is expressly stated that he could voluntarily bring the muscles into action as well as on the opposite side, although that half of the face remained almost motionless when it should have moved in common with the right side for the purpose of expression. This is exactly the opposite of what occurs when disease of the corpus striatum or other lesion of the motor tract causes paralysis of the face (cf. p. 563). In most of the cases reported by Ferrier, Jackson, Bourneville, and other writers quoted by Bastian, there were first spasms of the thumb, arm, foot, or leg, and afterwards paralysis. Sometimes, however, circumscribed convulsions supervened in a paralysed limb.

Lastly, instances have been observed by Gowers of congenital absence of one hand, and by Bastian of a wasted arm, associated with atrophy of the opposite ascending parietal gyrus; also of an amputated limb with similar atrophy of its motor area in the cortex.

The cerebrum outside the motor tract.—We have still to consider what "localising symptoms" may be present when a lesion is seated in the substance of one hemisphere, or in the superficial convolutions beyond the motor area. As we have seen, the cortical centres for the special senses are still imperfectly known, and tactile sensibility is almost always less affected than movement. Hence it is not surprising that no special localising symptoms can as yet be connected with cortical lesions of the front part of the frontal lobes, the temporo-sphenoidal or the occipital. In many cases the only symptoms are lethargy, listlessness, an oddness of manner, taciturnity, and unwillingness to speak, or loss of memory and impairment of intelligence—symptoms that we are accustomed to associate with diffused morbid changes affecting both hemispheres. These, it is interesting to remark, are the kind of symptoms which are found, in monkeys and in dogs, to result from ablation of the cortex outside the motor area.

The general symptoms of headache, vomiting, and optic neuritis may point to the presence of a tumour, but unless it happens to press on some nerve-trunk we have no means of determining its seat.

It is well to remember that cerebral hæmorrhage, the commonest of "destroying" lesions, is, as we found (*supra*, p. 557), rare in these "non-motor" regions compared with the corpus striatum, the pons, and the cerebellum. But tumours and cerebral abscesses are much less rare, so that we have sufficient evidence of their negative effects.

In a case under the writer's care in which the symptoms pointed to a cerebral tumour, its locality was ascertained by signs of pressure on the left orbit; the skull was therefore trephined, and a large growth was found in the anterior part of the frontal lobe. While these sheets are passing through the press, a patient under the care of Dr Shaw, whose sense of smell was noted to be decidedly deficient during life, died with symptoms of organic cerebral disease, and a cyst was found in the temporo-sphenoidal lobe.

The basal ganglia.—We have seen that ordinary hemiplegia does not, as was formerly supposed, depend upon lesion of either grey nucleus of the *corpus striatum*, but upon interruption of the motor tract as it passes between the caudate nucleus and thalamus (the internal capsule behind the genu), or upon severing of the white fibres of the external capsule or corona radiata outside the lenticulus, as they run from the motor area of the cortex.

Destructive lesions confined to the lenticulus or the cauda may produce no special symptoms.

The *thalamus* is more directly in the motor tract, but it is rarely the seat of disease, and the symptoms then produced are not characteristic. In the case of a boy in Guy's Hospital, which was published in the 'Pathological Transactions' for 1884, a tumour occupied the right thalamus. There was headache and double optic neuritis, with ptosis and slight motor paralysis of the opposite side affecting the arm more than the leg; no marked anæsthesia, if any, and no blindness or strabismus.

Lesions of the back of the thalamus have caused hemiopia, but there was probably pressure exerted on the optic tracts or the corpora quadrigemina.

The *pituitary body* is not infrequently the seat of a cancer, glioma, or other tumour. Three cases are noted in Dr White's list (p. 602, *supra*): one of these patients, a man of forty-five, with symptoms of tumour of the base, had a secondary growth in the lung. A fourth was a cystic tumour.

The *pinea* or conarium may contain a psammoma or sarcoma. Dr Heinrich Reinhold has collected four or five cases in a monograph ('Tumor der Zirbeldrüse,' 1886). In his case it was a glio-sarcoma.

Diagnosis.—The diagnosis of the affections described in this chapter involves two distinct questions. First, they have to be distinguished from other diseases of the nervous centres or of distant parts; secondly, they have to be differentiated from one another. The answer to the former question is often wonderfully positive and exact. To the young student—who perhaps knows the difficulty of distinguishing between tumours and other surgical affections of parts that can be seen and handled—nothing is more striking than the confidence with which the physician can sometimes assert the existence of a tumour in the cranial cavity.

Cases do, indeed, occur which are only cleared up in the *post-mortem* room. A man of whom little is known, or who has hitherto shown no marked symptoms of cerebral disease, may die in a succession of fits, or in coma of a few hours' duration, and it may be difficult to decide between tumour, cerebral hæmorrhage, thrombosis of an artery, and uræmia. Or, if he lives for two or three weeks, between tumour, abscess, and meningitis.

But, as a rule, the illness caused by a tumour, or a tubercle, or a syphilitic gumma in the brain begins gradually, and goes on for several months. In the cases that have occurred at Guy's Hospital within the last few years the duration of well-marked symptoms has generally been from three to nine months, but one patient had had fits for four years. Jackson has recorded the case of a woman who had optic neuritis and staggered in walking in 1865, and who did not die until the summer of 1872, when she had become insane—there was a growth springing from the "floor of the sphenoidal fossa." It may be affirmed that when cerebral symptoms of the kind described in the present chapter have lasted for more than five or six weeks, they are due either to a tumour or to red softening. Abscess is secondary to injury or some source of suppuration, and primary red softening is very rare.

There still remains another important source of difficulty. In women the symptoms of a cerebral tumour are sometimes so vague that for a long time they are mistaken for those of *hysteria*. The writer remembers a young woman in Mary Ward who had every symptom of hysteria, and who no doubt was highly hysterical. But Dr Willis, whose patient she was,

always asserted that there was more than hysteria. One morning, to the astonishment of nurses and students, she was found dead in her bed, and at the autopsy we found a cerebral tumour. A painter once died in Guy's Hospital of drowsiness and epileptiform fits, which were believed to be the effects of lead-poisoning; but a spindle-cell sarcoma of the size of a marble was found in the right hemisphere, with extensive yellow softening around it.

The ophthalmoscope.—In such cases, as in many others, the routine use of the ophthalmoscope is a great safeguard. The discovery of choked discs, or of optic neuritis, or of atrophy, goes far towards establishing the presence of an organic lesion. No doubt at first the significance of these appearances was rated too highly. When neuritis, or choking of the disc, affects one eye only, it is sometimes a sign that the cause lies in the orbit rather than within the skull. Mr Lawson brought before the Clinical Society in 1876 a case in which a hydatid cyst pressed upon the nerve behind the eye, and so caused great swelling of the disc on that side. Again, unilateral optic neuritis may be due to pressure upon the optic nerve between the chiasma and the optic foramen; a gumma at the base seemed to have acted in this way in a case recorded by Mr Hulke in the 'Ophthalmic Hospital Reports.' Dr Jackson has met with two cases in which the ophthalmoscope revealed an affection of one eye, dependent upon the presence of a tumour in the opposite cerebral hemisphere. In a patient of the writer's there was much more severe optic neuritis on the same side as a cerebral abscess than on the other. But it is a rule to which there are very few exceptions that both optic discs suffer from disease of the brain.

In some rare instances ophthalmoscopic changes seem to precede all other symptoms. A patient of Dr Allbutt had amaurosis from atrophy for three years before any signs of cerebral tumour began to manifest themselves, although these afterwards became well marked. But optic neuritis alone is not enough to indicate organic disease. In a series of unselected cases, recorded by Mr Hulke in the 'Ophthalmic Hospital Reports,' there are several in which optic neuritis, terminating in atrophy, seemed to be either spontaneous, or attributable to such vague causes as childbearing, lactation, leucorrhœa, sexual excesses, or to an antecedent attack of diphtheria or rheumatic fever; and in 1866 von Graefe spoke of it as sometimes due to menstrual disorders.

Even when unmistakable indications of cerebral disturbance are present, it is a question how far one is justified in concluding from ophthalmoscopic appearances that there must be organic lesion in the brain. In many of Mr Hulke's cases the other symptoms did not support the diagnosis of organic lesion of the brain. Three of them, all of which terminated in recovery, were thought to be probably examples of meningitis; but the evidence was imperfect. Another case would certainly have been regarded as one of ordinary epilepsy if the eyes had not been examined. Two patients, both advanced in years, had hemiplegia, and ultimately died of apoplexy: one, a man aged thirty-eight, attributed the affection of his eyes to watching a solar eclipse; another, a woman aged twenty-four, ascribed hers to standing in the garden with her head uncovered.*

* Dr Hughlings Jackson, who believes that double optic neuritis is almost certain evidence of what he terms "coarse disease" within the cranium, admits that he has himself met with a few instances in which, after death, no such disease could be found. Of one case of this kind he has published full details. A woman, aged thirty-four, had for about a year been subject to attacks of severe headache accompanied with vomiting; for three

In describing meningitis we shall mention cases in which symptoms very like those of that disease have been associated with double optic neuritis, but in which, although they terminated fatally, no lesion could be discovered either in the membranes or in the cerebral substance. Surely it is but common sense to suppose that, if one could see the state of the brain in cases which recover, it would be found equally free from obvious morbid changes. Ophthalmoscopic appearances have great value along with other symptoms in the diagnosis between organic and functional diseases, but they are not more pathognomonic than the rest.

Another question is whether any special inference can be drawn from the exact character of the ophthalmoscopic appearances in a case believed to be one of local organic disease of the brain. Meningitis often accompanies a gumma of the base; and a tumour in any part may set up extensive yellow softening. It might be thought that neuro-retinitis, as distinguished from choking of the disc, would indicate the presence of such secondary affections. But one of Mr Hulke's cases seems to show that the former change may depend upon the presence of a sarcoma attached to the floor of the skull, without there being any evident inflammation of the membranes or of the brain itself. Nor can simple atrophy of the disc, without antecedent neuritis, be taken as a proof of the existence of hydrocephalus.

To conclude, double optic neuritis certainly most often indicates a tumour, less commonly meningitis or hydrocephalus or tabes, rarely or never cerebral embolism, thrombosis, or hæmorrhage. It may occur in Bright's disease or after fever. Single optic neuritis rarely points to a cerebral lesion. Acute optic neuritis is often caused by a chronic lesion, as a tumour. Primary optic atrophy is not so often a symptom of local cerebral lesions as of more general diseases, such as tabes, general paralysis, and insular sclerosis; but when secondary it has the same significance as the descending optic neuritis, of which it is most often the effect. Atrophy, like neuritis, of one optic disc seldom points to cerebral disease; much more often to a "peripheral" lesion affecting the optic nerve or tract.

The *differential pathological diagnosis* between the several forms of local organic disease of the brain must usually rest on our knowledge of the most frequent, and therefore the most likely lesions in a given case. In a child there is a strong presumption in favour of *tubercle*. The older the patient,

months she had been blind. Her illness began by her being seized with vertigo and momentary unconsciousness, after which she had headache for four days. At another time the pain lasted for three weeks. She was admitted on December 19th, 1874. On January 6th, 1875, she had an attack of pain so intense as to make her toss her head from side to side, holding it in her hands, and crying, "Oh, my head! I don't know what I shall do." She retched and vomited frequently. Both optic discs were greatly swollen, and the veins in them were dilated and tortuous. After the 10th she sank gradually into what appeared to be natural sleep, which, however, passed into coma, and on the 12th she died by failure of the respiration. A tumour or some similar disease was confidently anticipated, but Dr Sutton, who made the autopsy, found only certain microscopical changes in the cortex.

Compare with this case one that was brought before the Clinical Society in 1876 by Dr Goodhart and Mr Higgens. A girl, aged twenty-one, was attacked with intense headache and vomiting on December 21st, 1874, at the very time when Dr Jackson's patient had just entered the London Hospital. Some months previously she had been stunned by a severe blow from a stone on her right temple. On the 24th there was well-marked double optic neuritis, her pulse was irregular and only 52 in the minute, and she had no fever. Afterwards she had paralysis of both sixth nerves, suffocative attacks in which she could hardly breathe, constipation, transient hemiplegia, delirium, and an affection of the speech, so that her mother could not understand her. But between the 6th and the 14th January, 1875, all her symptoms began rapidly to subside, and before long her impaired sight seemed to be the only thing that troubled her, except that she was unable to take solid food without vomiting.

the greater the chance that the lesion is some other form of tumour than tubercle; and above the age of forty the latter is very unlikely. To distinguish between tubercle and glioma or sarcoma is, however, of little practical consequence; what is really important is that one should never overlook *syphilis*. It is particularly to be noted that in many instances in which gummata are developed in the brain no nodes upon the bones can be discovered, nor any indications of past or present orchitis, iritis, or cutaneous eruptions. In only three or four of the ten fatal cases of this kind recorded by the author was it ascertained during life that the patient had suffered from any venereal disease. Dr Buzzard lays stress on the presence of a muddy complexion, and other signs of cachexia not traceable to any definite visceral disease, as pointing to syphilis. It is well known that in most cases the pains caused by this disease regularly recur, or at least undergo a marked aggravation in the evening. What seems to have more weight than anything else in suggesting syphilis as the cause of obscure nervous symptoms is the impossibility of referring them to any single lesion. Dr Jackson long ago insisted on the value of this principle, and Dr Buzzard has illustrated it by cases in point. Thus two of his patients had paralysis of one arm and of both legs at the same time; the inference was that there was an affection of the spinal cord as well as of the brain. Still secondary tumours are often multiple, and the presence of a primary new growth elsewhere is very apt to be overlooked. Thus a patient coming to a physician for headache and paralysis may very likely never mention that there has for years been a tumour in the breast, or that one testicle was excised some months before. Again, the original seat of the malignant disease may be some internal organ, where such an affection is difficult of detection. Out of sixteen cases at Guy's Hospital of secondary growths in the brain there were no less than six in which the starting-point of the mischief was a sarcoma surrounding the root of one lung, and in five of them this was not discovered during life.

Prognosis.—All that we know of the progress of cases of cerebral tumour would tend to show that they are inevitably fatal.*

Even when the local lesion in the brain is a syphilitic gumma the prognosis is not very favourable, so far as concerns the patient's ultimate restoration to health. For a time active treatment is generally followed

* The nearest approach to a recovery that I remember to have heard of occurred in a boy, aged fourteen, who was under my care in Guy's Hospital in 1867. About two years previously he had been taken ill with "pain in the back of the head, loss of sight, and fits in which he used to clench his hands." On May 1st, when he had been in my ward for three weeks, it is noted that "he lies apparently unconscious of everything, and cannot be roused. His head is constantly thrown backwards; and when he is touched there is a sort of opisthotonos. He is completely amaurotic; his pupils are equal and slightly dilated." On May 4th the report is, "He is slightly more conscious, he recognises his mother, and will raise his hand into the air when told to do so. His evacuations are passed involuntarily." During the next three months the chief change was that he slowly wasted away, until he was reduced to a mere skeleton; the only sign of intelligence that he ever manifested consisted in lifting his hand, as already described. But one day, in going round the ward, I spoke to him; and to the astonishment of everyone he slowly articulated a few words in reply. From that moment he began to improve. He took food well, regained flesh, talked more and more every day, got up, walked about the ward, and at last was discharged perfectly well except that he was blind. Afterwards he attended among my out-patients. I have no notes of his symptoms during this period, but I remember that he complained of paroxysmal headache, and of epileptiform fits. He was readmitted, and died. The notes of the autopsy have unfortunately been mislaid; but I recollect that there was an irregular calcareous mass, of about the size of a marble, embedded in the floor of the third ventricle, with some mucoid fluid round it.—C. H. F.

by very striking results; consciousness is regained, paralysis is recovered from, headache subsides, epileptiform convulsions cease to recur. But after an interval the symptoms return; perhaps the opposite limbs are now paralysed, or the affection may assume a paraplegic instead of a hemiplegic form. A second course of medicine may again be successful, but at last our efforts are baffled, and the patient succumbs. Such cases are often prolonged over a period of several years. On the other hand, it sometimes happens that the cure is permanent; and more often that each return is milder than the last, until the disease gradually wears itself out.

Treatment.—In the treatment of cerebral gummata one should not trust wholly to iodide of potassium, though it is desirable to give it at first, and often in very large doses, for its action is more rapid than that of mercury. But afterwards a mercurial course should always be prescribed. The bichloride may be given internally, or recourse may be had to calomel-vapour baths or to inunctions with blue ointment.

Such a line of practice often proves brilliantly successful, even when there was no proof that the symptoms were due to a syphilitic lesion. The question then arises whether the proof is supplied by the result of the treatment.

The palliation of symptoms is always possible. It there be epileptiform convulsions, full doses of bromide of potassium should be given. The same remedy will often relieve headache or giddiness. Or it may be necessary to administer opium or morphia by the mouth, or to inject the alkaloid subcutaneously. Dr Reynolds speaks highly of Indian hemp as sometimes altogether removing pain in the head. He also recommends the local application of ice.

The recent achievements of antiseptic surgery, and the power of localisation which we have seen that experiment and observation have now conferred on the physician, have led to the bold attempt to remove a cerebral tumour by trephining and enucleation. Mr Victor Horsley has published a remarkable series of not less than ten cases in which the seat of a cortical lesion was diagnosed and its removal accomplished ('Brit. Med. Journ.,' April 23rd, 1887). In half of these cases the morbid condition was not a new growth, but some inflammatory or degenerative change in the brain or meninges. However, in one it proved to be a tubercular tumour, in a second a glioma, in a third a large Pacchionian body, in a fourth a tumour weighing 4½ oz., and in a fifth a tubercular tumour. In the last of these cases the operation was fatal, in the second the glioma returned and proved fatal six months afterwards; in the three others the patient recovered from the operation, and the convulsions were rendered less frequent or the pain was removed. Mr MacEwen, of Glasgow, has also had successful cases, some of them as early as 1883 (see his address, *ibid.* August 11th, 1888).

It must be confessed that only a small number of cerebral tumours would be amenable to surgical treatment even if we could always accurately determine their situation. Many are too deeply seated, others are multiple; others not sufficiently circumscribed, others of malignant nature, and others only come under notice too late for treatment. The syphilitic growths, moreover, may be better cured by drugs.

A hundred cases from the records of Guy's Hospital were reviewed, with reference to the possibility of operation, by Dr Hale White ('Guy's Hosp.

Rep.,' vol. xliii, p. 117). He concluded that not more than three tubercular tumours, not more than four or five gliomata, and only one sarcoma, two cysts, one myxoma, and two tumours of doubtful origin—in all ten certainly, and four probably, of the 100—were removeable by operation, provided that their exact seat had been previously ascertained.

CEREBRAL ABSCESS.—This disease, though so different pathologically from a cerebral tumour, resembles it in its clinical characters, and hence is for practical purposes treated of here.

It is not a common malady, but is very dangerous, and affords a most instructive example of the unforeseen practical results which follow from thorough scientific investigation of diseases.

Ætiology.—The most important fact which was established by Sir William Gull in his papers on cerebral abscess in the 'Guy's Reports' for 1857 is that this affection is never primary nor idiopathic; it is due either to general pyæmia, or to injury or disease of the skull involving local purulent infection.

Its most frequent origin is from *diseases of the ear*, especially suppurative inflammation of the tympanum. Otorrhœa, if prolonged, always involves the risk of extension of mischief through the bone to the internal surface of the skull. Hence, no one with a chronic discharge from the ear should be accepted for life assurance at ordinary rates. In the 'Medical Times and Gazette' for 1863 a case is recorded of a patient who for several years had a discharge from the ear, but who lived to the age of sixty-six, and then died of a cerebral abscess; and it often happens that an aural affection which had been present from early childhood kills a grown-up man or woman. In many instances the several stages of the morbid process are plainly traceable after death. The tympanic cavity is found to be bare and carious, or necrotic; the dura mater over its roof is raised from the bone by pus, or it is softened and sloughing; the arachnoid and pia mater are adherent at this point, and close to it an abscess is found in the temporo-sphenoidal lobe. Or, the caries may pass from the mastoid sinuses or from the petrous bone to the posterior fossa of the basis cranii, and then the abscess occupies the corresponding half of the cerebellum. Among eighteen successive cases at Guy's Hospital there were twelve in which the temporal lobe of the cerebrum was the seat of the abscess, three in which it lay in the cerebellum, two in the centrum ovale, and one in the pons.

The late Mr Toynbee believed that abscess of the cerebrum usually follows from caries of the tympanum, abscess of the cerebellum from phlebitis of the lateral sinus, and abscess of the bulb from caries of the labyrinth. The third situation is too rare to be taken into account; but Gull, and subsequent German writers, confirm Toynbee's statement of the connection between disease of the middle ear and abscess of the cerebrum, and between the disease of the mastoid sinuses and abscess of the cerebellum.

According to Huguenin and Meyer, the right side of the encephalon is much more apt than the left to be affected with abscess from disease of the ear; and, among twenty-four cases collected by Gull and Sutton, the right side was affected in no less than eighteen. But it is curious that of the eighteen cases that have since occurred at Guy's Hospital, in nine the abscess was on the left side, and in nine on the right.

Aural surgeons formerly laid stress on the diagnosis of caries of the

tympanum, as indicating the danger of extension to the brain, and they did not hesitate to pass a probe in search for rough and denuded bone. But apart from the risk of breaking through the wall, and so of setting up the very mischief which is dreaded, experience has shown that the detection of caries is less important than was supposed. In many instances of cerebral abscess set up by inflammation of the middle ear, the bone is found after death to be healthy. There is more than one route by which the morbid process may reach the brain. It may pass along the bony canals which transmit the superficial petrosal and other veins, or through the spaces in the diploë which convey vessels from the tympanum to the dura mater. A curious circumstance is that in many instances there is a tract of apparently healthy cerebral substance between the wall of the abscess and the petrous bone.

When the suppuration of the ear assumes a putrid character the danger of meningitis or cerebral abscess is the greatest. The suppression of the discharge from the external meatus and a sudden increase of pain in the ear are bad indications, for they denote swelling of the mucous membrane and increased tension in the tympanum. But in some cases there is no pain at all: there may even be no otorrhœa, for the secretion may be retained behind a perfect membrana tympani; and thus, unless one carefully tests the patient's hearing, we may easily overlook the fact that he has anything the matter with his ear.

Another, but a far less frequent cause of abscess of the brain, is chronic *disease of the nose.* Two such instances were recorded by Gull in the 'Guy's Hospital Reports' for 1857. Each patient had suffered from a discharge from the nostrils; in one case the abscess was in the middle lobe, in the other in the anterior lobe. Other writers have given cases in which a *nasal polypus* was the starting-point of the mischief. The author once made an autopsy in which an ulcerating *epithelioma* of the lip and cheek extended to the base of the skull along the third division of the fifth nerve, and set up an abscess in the middle lobe of the brain. Necrosis or *caries of the calvaria* from any cause, if attended with sloughing of the dura mater, may have a like effect. Another source of suppurative meningitis or of cerebral abscess is *carbuncle* of the face, particularly of the upper lip.

General *pyæmia* sometimes leads to the formation of one or more abscesses in the brain, as in other parts of the body. In records of examinations at Guy's Hospital (during the same period within which occurred the eighteen cases above mentioned of cerebral abscess from disease of the ear) there were nine instances of abscess as a part of general pyæmic infection.

There is a curious group of cases of cerebral abscess, which are secondary to pre-existent suppurative inflammation in a remote part of the body, but in which there are at no period any symptoms of blood-poisoning, and in which no pyæmic abscesses are found anywhere but in the brain. Sir William Gull first showed the ætiology of such cases, although a similar instance had before been recorded by Abercrombie. The most remarkable point is that the *lung* is generally the seat of the primary lesion which leads to the abscess in the brain. At Guy's Hospital within a few years we had six cases of this kind; six others are given by Gull and Sutton in the second volume of 'Reynolds' System of Medicine,' and some have been recorded in Germany by Biermer, Huguenin, and Meyer. The supposition has generally been that the cerebral inflammation is set up by a portion of thrombus washed out of a pulmonary vein, and

carried to the brain in the blood; and Böttcher is said to have found in the floor of an abscess of the brain, which was secondary to a pulmonary abscess, some pigment which he was able to identify as having come from the lung. The nature of the thoracic disease has varied in different instances. Adding the cases which have recently occurred at Guy's Hospital to those related by Gull and Sutton, we obtain a series of twelve examples of this form of abscess of the brain. Among them there are three in which the primary affection was empyema (cf. 'Path. Trans.,' vol. xxviii, p. 4), two of tubercular phthisis, two of some form of acute pneumonia, one of simple bronchitis; in each of the remaining four it seems to have been pulmonary cirrhosis (chronic interstitial pneumonia), with dilatation of the bronchial tubes, or a sloughing cavity in the indurated tissue. Huguenin places bronchiectasis with stagnant putrid secretion at the head of the list of pulmonary diseases which give rise to cerebral abscess. It is important to note that the mischief in the lung may be altogether latent. In one of the above cases Dr Moxon says that he almost despaired of finding a primary lesion, until at last he discovered that the mucous membrane of the right bronchus was extensively ulcerated, with its cartilages exposed and necrosed.

We must remember that general pyæmia may have an internal source: as ulcerative endocarditis or acuto osteomyelitis. Either of these sources of infection may lead to abscess of the brain with or without meningitis.

Another cause of suppuration within the substance of the brain is direct *injury to the head*, as from a fall or blow. Generally the skull is fractured, and serious symptoms are present from the time of the accident until death releases the patient from his sufferings. Such cases come under the care of the surgeon, and do not require further mention here; but in exceptional instances the fact that the head has been injured may be overlooked, or the accident may have occurred some time previously, and been forgotten; and thus the physician may find himself in attendance.

Sir William Gull records the case of a boy, aged sixteen, who was in 1844 taken into Guy's Hospital for what appeared to be slight fever. After he had become convalescent he was attacked with cerebral symptoms, and ultimately fell into a comatose state. His friends then for the first time mentioned that three weeks before his admission he had been stunned for a minute or two by falling backwards from a cart, so as to strike his head upon the ground. There was neither wound nor bruise, but it seems that he complained of nearly constant pain in the head up to the time of his coming into the hospital. He died about two weeks after the accident; and a large abscess was found in the left hemisphere. There was also an abscess in the situation of the sphenoidal sinuses beneath the carious olivary process of the sphenoid bone. Could this have been caused by the fall? and, if so, was it not the cause of the cerebral abscess?

Another case occurred to Dr Tuke ('Med. Times and Gaz.,' 1861, i, p. 196). It is that of a man, aged forty-seven, who died after a week's illness with cerebral symptoms. A few months previously he had fallen from a ladder and struck his head, without any severe symptoms immediately following. Dr Tuke believed that the accident was the cause of the cerebral symptoms; but it should be noted that, although the patient had suffered from "chest symptoms" a year previously, there is no mention of the state of the lungs at the autopsy.

One would be the more ready to attribute a cerebral abscess, for which we could find no other cause, to an injury of the skull that occurred

within a year or two previously, because it appears that there is scarcely a case to be met with in which one is absolutely driven to admit that the abscess is primary and spontaneous. Among seventy-six cases collected by Gull and Sutton for the 'System of Medicine' there are, indeed, a few in which no cause was found; but the only one of which it can be said with certainty that the autopsy was complete is the last of the series, that of a man who died in Guy's Hospital in 1863, and whose body was examined by Dr Wilks. He was employed at a music-hall, and some years before his chest had been crushed in an accident, but he was not known to have injured his skull. However, he had led an irregular life, and might easily have received and forgotten such an injury.

Of 100 cases collected by Mr Barker ('Lancet,' June 11th, 1887), 29 were due to disease of the ear, 27 were traumatic, 20 were associated with suppuration in the lungs or liver, and 7 were due to general pyæmia.

In his recent 'Gulstonian Lectures' (March, 1890) Dr Pitt has recorded 56 cases of cerebral abscess from the records of Guy's Hospital, and of these 18 were due to disease of the ear, 1 to disease of the nose, 10 to injury of the skull, and 3 more to cranial periostitis or caries; 3 to invasion of tumours of the skull, 8 to primary disease of the lung, 9 to general pyæmia, and in 4 no certain origin could be ascertained.

Cerebral abscess, consecutive to disease of the ear, is about equally frequent in males and in females; of the cases secondary to chronic pulmonary affections the larger proportion seem to occur in men.

The great majority of cases, from whatever cause, are met with in persons between fifteen and thirty years old.

Of Dr Pitt's 56 cases, only 4 of non-traumatic origin occurred in children under ten, and only 9 in patients above forty.

Anatomy.—Abscesses of the brain arising from different causes are to some extent different. Those which result from injury are almost always solitary, and so are those which are secondary to affections of the ear or nose. Out of twenty-seven cases due to aural disease, collected by Gull and Sutton, there are only two in which more than one abscess was present; in one the cerebellum contained three abscesses, in the other there was one in the cerebellum, as well as one in the cerebrum. On the other hand, fourteen cases of general pyæmia, in which the brain was the seat of suppuration, yield eight in which the abscesses were multiple, and in most of them there were four, five, or more in different parts of the cerebral substance. So, again, in seven out of eleven cases consecutive to affections of the lungs, the abscess was multiple. The presence of numerous centres of suppuration may therefore go far towards determining the real origin of an abscess in an autopsy, and this might be of juridical as well as of pathological interest.

The cerebral abscess caused by disease of the ear or nose is generally ill-defined, its wall shreddy, and surrounded by softened cerebral substance; but sometimes it is enclosed in a thick capsule. In pyæmia the abscesses seem to be very rarely circumscribed; but in Dr Moxon's case, which lasted eighteen months, the limiting membrane was so firm that it could be lifted out of the brain-tissue in which it lay. When the affection is secondary to disease of the chest there is almost always a well-marked capsule. Sir William Gull stated that the cyst wall is made up to a great extent of spindle-cells. Rindfleisch has since shown that they constitute its middle layer, there being outside them a plane of fibrous tissue, while

the cavity is lined with embryonic tissue, the superficial cells of which are opaque and yellow from fatty degeneration. Even in abscesses of recent formation the pus is commonly greenish and viscid, although it has an acid reaction; but in those of long standing it is often as thick as mucus, of a bright green colour, and alkaline. It may be odourless, or have a nauseous sickly smell, or (when arising by extension from bone disease with necrosis) be horribly fœtid. Mixed with the pus corpuscles is much granular matter and fat, probably derived from the brain-tissue replaced by the abscess; and in very old cases one can hardly recognise any pus-cells; they have undergone complete degeneration, and nothing is left but débris.

It is only in cases arising from injury that the commencement of the cerebral suppuration can be fixed with sufficient accuracy to decide as to the length of time required for the production of a capsule. The evidence collected by Lebert and Meyer on this point goes to show that by the end of the third week the abscess cavity may be found circumscribed, but that a definite membranous cyst wall is not found before the sixth or seventh week, and sometimes not until a far longer period has elapsed. Gull observes that this might become a medico-legal question in some cases of a man dying of cerebral abscess after receiving a blow, if an interval had elapsed so that no direct clinical connection could be traced between the supposed cause and the effect. He cites one instance in which the absence of a limiting membrane was taken as proof that the disease could not have been the result of a severe fall eighteen months previously; and another, in which its presence showed that the suppuration in the brain was not due to an attack of smallpox which occurred within the last three or four weeks before death. Unencapsuled abscess may form in seven days.

An abscess of the brain, when solitary, generally reaches a considerable size before it destroys the patient. It is frequently as large as a hen's egg, and sometimes larger. It often reaches close to the surface of the hemisphere, and is said sometimes to break through beneath the pia mater. It is also said that pus from an abscess in the brain may be discharged through the auditory meatus producing "cerebral otorrhœa." So, again, an abscess set up by caries in the nose may break through the ethmoid bone into the nostrils. Usually a large abscess within the hemisphere pushes inwards towards the lateral ventricle. At Guy's Hospital this was found in four or five cases of suppuration following caries in the ear; and it is by no means infrequent in cases which are secondary to empyema or bronchiectasis. The pus may be found collected in one of the cornua, into which it has fallen by gravitation, or the whole of both lateral ventricles may be full of pus, with the ependyma intensely inflamed, thickened, grey, and velvety; the morbid action may even spread through the third and fourth ventricles to the subarachnoid spaces of the brain and spinal cord.

Symptoms.—The symptoms of abscess of the brain vary widely in different cases. It has been said that there may be absolutely none, and the affection be accidentally found after the death of the patient from some other cause. This, however, may be justly doubted. In the large majority of cases, symptoms are present for a much shorter period than that during which the abscess in the brain must have been forming; in other words, the disease is commonly latent during part of its course. This latent period may be only a week or a fortnight, but occasionally it extends to several months. In cases of general pyæmia, the occurrence of suppuration in the

brain may be masked under the delirium and stupor which so often accompany severe blood-poisoning.

The earliest symptom of cerebral abscess is, as a rule, *pain*. This varies greatly in severity. In cases secondary to otorrhœa it is the most agonising, in cases of pyæmia least so. Gull and Sutton speak of one patient as continuously holding his head with both his hands, and of another as walking about with his hands pressed against one side of his head, and calling out, "Oh my head! oh my head!" Another could not help screaming; and although perfectly sensible, would tear and bite anybody or anything near him, at the same time expressing contrition for what he was doing. The pain is generally continuous; but it is sometimes intermittent, especially at first, and is usually increased by drink or by violent movements. Anstie mentions the case of a boy who for three months complained of no symptom whatever, except of a pain which came on in attacks very closely resembling those of migraine, not oftener than once in ten days or a fortnight, and lasting for some hours at a time, nearly always ending in vomiting, and disappearing after sleep. In some instances the seat of the pain corresponds closely with that of the abscess; Gull and Sutton record the case of a boy who had almost constantly a burning pain over the front and right side of the head, and in whom the disease was in the anterior lobe of the right hemisphere. But they go on to speak of a patient who had an abscess in the cerebellum with pain in the forehead, and of another who complained of the left side of his head, but had an abscess in the right middle lobe.

Next to pain, *vomiting* is the most important symptom—occurring frequently, without relation to the ingestion of food, and without any symptoms of gastric irritation.

Much less frequently an *epileptiform seizure* forms the starting-point of the symptoms; and such seizures may be repeated at intervals for a considerable period, before any further sign of illness manifests itself. Or the first thing noticed may be a dulness of expression, a change of disposition from cheerful to morose or melancholy, a disinclination to speak, loss of memory, or inability to sleep. Gull lays stress on rapidly increasing emaciation as having been a principal symptom in some cases. *Rigors* may occur, sometimes with such regularity that the case might be mistaken for one of ague. The pulse is sometimes slow; Huguenin relates a case in which it fell to fifteen and even to ten in the minute.

The *temperature* is often normal or subnormal, rarely raised unless there is meningitis or pyæmia as a complication. In a case under the writer's care in January, 1886, the patient, a girl about twenty, had a temperature of 106°, with symptoms of pyæmia and basal meningitis. There were found, beside suppuration of the liver and other organs, a large abscess in the left hemisphere, which had opened into the ventricle, a second in the lower part of the ascending parietal gyrus, and a third in the præcuneus. There had been no motor paralysis.

The *pupils* are often sluggish or unequal, sometimes dilated. The *optic discs* are sometimes seen with the ophthalmoscope to be "choked," or œdematous, or in a state of acute optic neuritis. In a case of the writer's this was much more marked on the side of the abscess, but this is exceptional; indeed, the fundus in several cases of cerebral abscess has been normal. Dr Pitt found optic neuritis more common from thrombosis of the sinuses.

Localising symptoms.—In the symptoms hitherto mentioned there has been little or nothing to indicate that one part of the encephalon rather than another is the seat of disease. But in exceptional cases "localising" symptoms are not wanting. Aphasia may be present, which shows that the abscess is in the back part of the left frontal lobe. Much more frequent is hemiplegia, partial or complete. This indicates that the part affected is near the fissure of Rolando; or that the inflammatory process extends inwards, so as to involve the internal capsule or corpus striatum. We have already cited a case of Hitzig's in which spasms confined to certain muscles were set up by a small abscess limited to a small part of the cortex. Sir William Gull has recorded the case of a gentleman who on many occasions had a sudden convulsive affection of his right arm—so violent that he had to support himself by holding on to the table with his other hand, and yet so devoid of pain that he was amused by it; after death a large abscess was found in the occipital lobe.

Tenderness on percussion of the skull may occasionally be elicited, and may be a valuable localising symptom.

Huguenin thinks that the rupture of an abscess into the ventricle may sometimes be recognised by the supervention of spasms in both sides of the face, or in both legs, without loss of consciousness; and he gives cases in which these symptoms were present.

It seems to be very doubtful whether there are any localising symptoms peculiar to abscess of the cerebellum. Huguenin says that the pain is not only referred to the occiput, but often extends down the back of the neck. He also states that the pupils of both eyes are commonly dilated, that vomiting is peculiarly severe, and that the gait is sometimes unsteady, like that of a person affected with locomotor ataxy. In one case which occurred at Guy's Hospital the patient was so feeble as to be hardly able to sit up in bed; but in that instance (as in many other cases of cerebellar abscess) the lateral ventricles of the cerebrum contained a large excess of fluid, a result, in all probability, of pressure upon the veins of Galen.

Huguenin finds that about one fifth of the total cases of cerebral abscess are situated in the frontal lobe, one eighth in the occipital, one fifth in the temporo-sphenoidal, a very few in the parietal, fewer still in the pons or bulb, and most of the remainder in the cerebellum.

In Dr Pitt's series from Guy's Hospital, abscesses from all causes were found 18 times in the frontal lobes, 14 in the temporo-sphenoidal, 6 in the occipital, 5 in the parietal, 8 in the cerebellum, and once in the pons.

Mode of death.—None of the symptoms which have been described are such as would suggest to an unskilled observer that the patient's life is in imminent danger. But after they have been present for several days or even weeks—or, sometimes, without any warning symptoms whatever—he falls into a state which is obviously most alarming. Violent delirium may set in, followed by stupor and coma; or a severe epileptiform fit may occur, after which he may never regain his consciousness. In 1876 a girl, aged eighteen, was admitted into the Clinical Ward one afternoon at five o'clock. She had for six days been suffering from sickness and diarrhœa, with severe headache, so that she was said by the medical man who attended her to have typhoid fever. She then spoke rationally and answered the questions that were put to her, but seemed rather strange in her manner. At eight o'clock the same evening she suddenly made a great noise; the house physician was hastily summoned, and found her partially

insensible, but capable of being roused so far as to say that she was going to die. She seemed to have loss of power in her left arm and leg. An hour later she all at once ceased to breathe. Artificial respiration was kept up, and the heart continued for some little time to beat rapidly, but it soon slackened, and in ten minutes she was dead. We found four or five abscesses in the posterior and middle lobes of the right hemisphere.

The final stage of a cerebral abscess is seldom of long duration; but it may last for a week, and in exceptional cases longer still, during which time the patient is alternately delirious and in a state of stupor, and passes his evacuations under him. Sometimes there is a transient recovery from such symptoms, followed by their return, and by speedy death.

Diagnosis.—That the diagnosis of abscess of the brain is often beset with difficulties must be sufficiently apparent from what has been said of its symptoms and of the conditions under which it occurs. In cases of supposed ague, of hysteria, of enteric fever, and of neuralgia, it is needful to bear in mind cerebral abscess as possible. Between abscess and other organic cerebral diseases, particularly tumour and meningitis, there is no positive criterion.

In practice we recognise abscess of the brain not so much by its symptoms as by our pathological knowledge of the causes to which it is commonly due. Since it seldom, if ever, arises spontaneously, this would give us a good opportunity of diagnosis, but for the fact that both the patient and his friends too often deny the existence of these several causes, otorrhœa, deafness, bronchial and pleuritic disorders, and other sources of pyæmia. Moreover, all the affections that may set up suppuration in the brain are also liable to give rise to other forms of cerebral disease. Thus injury is not infrequently followed by meningeal apoplexy. Again, we can seldom speak with certainty of cerebral abscess as being consecutive to any pulmonary affection, unless we are in a position to exclude the possibility of its being phthisis; for that disease is sometimes accompanied by solitary tubercle of the brain, and very often sets up tubercular meningitis, which is itself a very insidious malady, and attended with the most varied symptoms. Lastly, disease of the ear may either be the starting-point of general meningitis, or may cause thrombosis of the lateral sinus (cf. *infra*, pp. 648, 676).

The *prognosis* of cerebral abscess is fatal, and its only possible *treatment* is surgical.

Mr Hilton used to quote in his lectures a case of Dupuytren's, in which he trephined the skull, expecting to find pus under the bone; he then incised the dura mater, and finally thrust a bistoury into the brain, gave exit to a quantity of pus, and cured the patient. Similar cases have occasionally been recorded since. In 'Ziemssen's Cyclopædia' Huguenin mentions twenty-six cases of supposed success in opening abscesses of the brain. The operation was a much more desperate one before the methods of antiseptic surgery were adopted.

When the abscess results from otorrhœa the mastoid bone has been trephined and the pus successfully evacuated.

In a patient under the writer's care in Guy's Hospital in July, 1879, the symptoms and previous history pointed strongly to an abscess in the anterior parietal region of the left side. Mr Lucas trephined, opened the dura mater, and incised the brain, but without result. No harm was done, and the symptoms of pressure were somewhat relieved; but when death occurred a few days later we found a focus of red softening with infiltrated pus in the corona radiata, close to the part operated on.

In March, 1890, a girl of about twenty was admitted into Mary Ward with otorrhœa, severe headache, vomiting, low temperature, and acute optic neuritis, particularly on the side of the diseased ear. Mr Jacobson trephined the skull and opened an abscess in the temporo-sphenoidal lobe, which, after a second operation, ceased to discharge. The symptoms have disappeared and the patient is convalescent.

With increased means of accurate localisation and advancing surgical experience, we may confidently expect that the number of cases of cerebral abscess successfully treated by operation will increase.

There are now many recent cases of successful surgical treatment of this otherwise fatal disease: among them may be mentioned those of Dr Truckenbrodt in 1886, of Mr Barker (1886 and 1888), Mr MacEwen (1887, who reports twelve cases in all), Mr Horsley (1888, who reports eleven), Prof. Bergmann (who reports four cases from Berlin), Sir Wm. Stokes (a successful case from Dublin), and several from the United States.

RED SOFTENING.—*Ramollissement rouge.*—The morbid condition so named is not very common, and is one of the most curious to which the brain is liable. It is attended with great swelling; convolutions so affected are broader than natural, and the sulci between them deeper; and the corpus striatum or thalamus is rounded, prominent, and generally increased in size. As is implied by the name, there is a marked diminution of the natural firm consistence, and the colour is altered; the cortex assumes a deep purple tint, and the white substance becomes pink or red, with numerous minute ecchymoses. Under the microscope the capillary and other vessels are found dilated and engorged; blood-corpuscles are seen among the nervous tissues, and if not very recently extravasated they are found fused together into shapeless masses. According to Rindfleisch, pus-cells are collected about the smaller blood-vessels. Moxon, however, says that he has often been surprised to find how slight were the histological changes in some cases of this kind: the elements of the tissue were softened and granular, but they still retained their form, and no characteristic inflammatory products could be recognised.

Most pathologists speak of suppuration of the brain as a further stage of red softening. It is true that in cases of pyæmia one sometimes finds reddened patches apparently antecedent to the formation of the pus; indeed, a similar condition is now and then seen in the neighbourhood of an abscess. In the latter case, however, it might fairly be regarded as the result of a distinct morbid process affecting the brain-tissue round the wall of the abscess, just as it may affect that which surrounds a tumour or an apoplectic clot. Moreover, when several suppurating cavities are found in the same hemisphere—however small and recent they may be—the intervening cerebral substance is commonly pale and of firm consistence. Lastly, the causes of red softening are different from those of abscess.

One of these causes is injury. Some years ago a woman died in Guy's Hospital, who had fallen three or four months previously, and struck her head against the wall. Three weeks before her death she had a fit, which was followed by partial left hemiplegia, affecting the side of the face and tongue, and accompanied with ptosis. At the autopsy, all the parts at the base of the brain were found by Dr Wilks to be in a state of softening, "partly red and partly white;" one third of the thickness of the pons was so affected, and nearly the whole of the crus cerebri.

Again, red softening may accompany an inflammation of the membranes, as tubercular meningitis. We have already spoken of it as sometimes arising in the neighbourhood of an apoplectic clot (p. 557), round a tumour (p. 559), or in a part of the brain deprived of its blood-supply by thrombosis or embolism (p. 554).

It is a question still undecided whether red softening of the brain ever occurs as a primary and independent morbid process. In the records of examinations at Guy's Hospital there are very few cases that could be so interpreted. In two instances the occipital lobe of the left hemisphere of the brain, and a considerable part of the cerebellum on the same side, presented the change in question; but in each of them the cardiac valves showed recent vegetations, so that it seems probable that the affection was dependent upon embolism of some of the smaller arteries.

In 1876 the author made an autopsy in which parts of the right superior and middle frontal convolutions were swollen, soft, and of a grey-pinkish colour. There was no caseation, and no definite edge to suggest the presence of a new growth; so that the lesion would have been regarded as primary acute inflammation had not the microscope revealed the presence of a large number of oval and round cells infiltrated between the nerve-fibres. It was a diffused glioma. We must therefore suspect any case of supposed primary red softening, unless a careful examination of every part of the affected structures has been made.

Some years ago a woman, aged twenty-six, died in the hospital, after an illness of three months' duration. The falx cerebri was found adherent to the anterior parts of both hemispheres by granulation-tissue. On section the frontal lobes appeared of a brick-red colour; their cineritious substance was swollen, and the boundary-line between it and the white matter was ill defined. On the left side this red colour extended down to the lateral ventricle. The affected parts were rather harder than natural; but in all other respects the disease corresponded perfectly with the descriptions which writers have given of local inflammation of the brain; and unless there was a new growth which was overlooked, it must have been of that nature. The microscope only showed corpuscular infiltration, with compound granule-masses.

Huguenin, who doubts the existence of "spontaneous encephalitis," nevertheless describes various retrograde changes as consecutive to red softening. He says that the patches may either subside entirely, or pass into a condition of yellow softening with cavities full of serum, or undergo cicatrisation, or become converted into tough, dirty-white, indurated masses. It is difficult to tell on what evidence we could conclude that the conditions in question had followed red softening rather than an effusion of blood or obstruction of an artery.

DISEASES OF THE MENINGES AND VENTRICLES OF THE BRAIN

Pachymeningitis hæmorrhagica.

AMONG the most frequent and the most fatal of all cerebral diseases are those which depend on inflammation of the meninges.

It was once usual to describe separately "inflammation of the dura mater" (*pachymeningitis*), "arachnitis," and inflammation of the pia mater (*leptomeningitis*). It is true that various diseases of the bones of the skull—such as, for instance, caries of the petrosal—may give rise to ulceration or sloughing of the corresponding part of the dura mater. But that local affection requires no special notice; it is only preliminary to diffused inflammation of the pia mater, or to a cerebral abscess; and upon these conditions all the clinical and pathological interest of the case is centred. Again, there is not any disease that can be said to be strictly "arachnitis." Pus or purulent lymph is sometimes found in large quantity within the arachnoid cavity; and its presence or absence constitutes one of the distinctions between two different forms of meningitis. But the limitation of suppuration to a supposed serous sac without implication of the pia mater is unknown to the surgeon as a result of any kind of injury to the skull; and certainly the physician never meets with it. If the arachnoid were perfectly analogous to the pleura or the peritoneum, we should expect it to be liable to serous inflammation attended with the exudation of lymph and serum, like the other great divisions of the pleuro-peritoneal space. But no such anatomical analogy exists: the "parietal layer of the arachnoid" is the endothelial lining of the dura mater; and the "visceral layer" is nothing but an outermost condensed stratum of the pia mater. The arachnoid cavity is now sometimes called the subdural space.

The following diseases are all forms of *meningitis*, *i. e.* inflammation of

the pia mater, or *leptomeningitis*. They all are seated mainly in the loose tissue of the pia mater, and are all diffuse, not focal nor disseminated; but they differ much in intensity, and still more in their causes.

TUBERCULAR MENINGITIS.*—This is the most frequent of all diseases of the nervous centres, but notwithstanding its frequency and the fact that it has been known for more than a century, its real pathology has been recognised only during the last sixty years. The first detailed account of its symptoms was published in 1768 by Dr Robert Whytt (a man of eminence in his day at Edinburgh) under the name of dropsy of the brain; and in the early part of the present century it became generally known as "acute hydrocephalus"—a designation which was retained by Sir Thomas Watson, as recently as 1857, as being "so established, both among medical men and with the public, that he could not venture to propose any change." He was, however, well aware of the fact, first pointed out by Papavoine in 1830, that the essential morbid change is the presence of tubercles in the membranes, and that the fluid within the ventricles is of quite subordinate importance. Since inflammatory products are also present, the name of tubercular meningitis, suggested by Bricheteau, in 1814, is obviously appropriate, and has now met with universal acceptance.

Morbid anatomy.—The appearances found after death vary considerably in different cases, and in different parts of the brain. As a rule, the most marked lesions are found at the base. The diamond-shaped space bounded by the optic tracts and the crura cerebri is filled with gelatinous or puriform lymph, which also envelops the great arteries arising from the circle of Willis and their branches. The inflammatory process may extend along the Sylvian fissures until it occupies a great part of the convex surface of the brain. Generally, however, the surface of the hemispheres shows no obvious changes; the sulci may be reduced in size as the effect of pressure. A large quantity of lymph is often spread out over the pons and bulb, and it may be traceable in the subarachnoid space as far as the lower end of the spinal cord. Almost invariably there is a yellowish patch upon the upper surface of the cerebellum, close to the opening of the veins of Galen; and sometimes the velum interpositum and choroid plexuses are infiltrated and thickened. The fluid within the ventricles is increased in quantity and is generally rather turbid. Its specific gravity may be raised to 1010; it yields a more or less distinct coagulum on boiling, and exhibits leucocytes under the microscope. The ependyma is often granular. The adjacent parts of the brain are usually much softened. The fornix and septum lucidum may be almost diffluent, and even the great basal ganglia may have their consistence so much reduced that they fall into a shapeless pulp as soon as they are removed from the skull. This "white softening" appears to be due to a mere disintegration of the tissue, for no exudation cells are discoverable. It is certainly not a mere result of *post-mortem* maceration.

In addition to acute basal meningitis, more or less numerous tubercles are to be found. If they are but few, they are most easily recognised in the Sylvian fissures or in the folds of pia mater dipping into the sulci; they appear as minute grey dots, adherent to the smaller arteries or to delicate filaments of connective tissue. When they are abundant, they may become fused together so as to ensheath an artery in a granular mass. Some are

* *Synonyms.*—Acute Hydrocephalus—Basal meningitis—Idiopathic infantile cerebro-meningitis—Leptomeningitis tuberculosa.

generally found caseating, and their opaque yellowish colour enables them to be more easily recognised. Cheesy aggregations of considerable size may be found embedded in puriform lymph. If the tubercles are present in very large numbers, they may be seen thickly scattered as milk-white spots beneath the visceral arachnoid, especially on the under surfaces of the cerebral lobes. They may also be developed in the form of very minute transparent granules upon the inner aspect of the dura mater lining the fossæ of the skull, and (according to Huguenin) between the two layers of that membrane, close to small twigs of the middle meningeal artery. In the vertebral canal they are found both on the smooth side of the spinal dura mater and on the visceral arachnoid. Within the ventricles they occur only in the choroid plexuses. They sometimes grow from the processes of the pia mater which pass down between the convolutions, appearing as whitish-yellow streaks along the small arterial branches in the cortex. Dr Gee mentions a case in which the capillary vessels throughout one hemisphere were studded with miliary tubercles, which remained after the softened cerebral substance had been all washed away.

In one instance the author found one hemisphere affected on its convexity with tubercular meningitis, while the left side of the brain and its base seemed to be entirely free. Huguenin describes two similar cases in which the affection was limited to the territory of a Sylvian artery; and Dr Pitt records others ('Brit. Med. Journ.,' 1890, i, p. 772).

The meninges covering the bulb and cord are often affected as well as those of the brain.

Pathology.—Tubercular meningitis very seldom occurs as an independent malady. In almost every instance it is either secondary to some chronic tubercular disease, for which the patient is already under treatment, or else it is only part of a general acute tuberculosis. Often it is both consecutive to a local chronic lesion, and also associated with the simultaneous development of recent tubercles throughout the body.

Of one hundred and twenty-four cases of tubercular meningitis at Guy's Hospital, sixty-five occurred under the age of twenty; fifty-nine between twenty-one and sixty. Among the former there were thirteen in which the cerebral affection was secondary to disease of the hip-joint or spine, or some other malady capable of clinical recognition; among the latter there were twenty-eight such cases, mostly pulmonary phthisis. In eighty-six of the one hundred and twenty-four cases there were miliary tubercles in the viscera or in the serous membranes. In only nine or ten cases is it distinctly stated that recent tubercles were present in the pia mater and nowhere else.

An interesting question concerns the relation of the tubercles to the lymph and other associated products of inflammation. The opinion expressed by Huguenin is that the miliary granulations are first developed, and that the pia mater tolerates their presence for a time, but that they afterwards excite inflammatory reaction. Rilliet had before put forth this doctrine. But, as Wilks and Moxon argued, if such a view were correct, one ought sometimes to discover meningeal tubercles in small quantities, unmixed with inflammatory products, in those cases in which acute tuberculosis destroys life by invading the lungs or other organs, and to find it unattended with the characteristic cerebral symptoms.

The author met with two instances of this kind. One occurred in a woman, aged thirty-two, who was admitted with an abdominal tumour that turned out to be the omentum indurated by tubercle. She was attacked

by hemiplegia, coma, ptosis, and delirium, and died in seven days. At the autopsy the brain and its membranes looked healthy, except for a single minute granule on a fold dipping into one of the sulci, and a little filmy material round one Sylvian artery. So slight was this change that if it had been observable on both sides it would have been passed by. But the microscope showed that even the apparently healthy artery of the opposite side, which had been set apart for the sake of comparison, had a distinct growth of tubercle about it; and the one white granule in the pia mater was already caseating in the centre.

The other instance is that of a man, aged fifty, who became suddenly unconscious on May 2nd, 1876, and was brought to the hospital in a state of coma, with stertor and right hemiplegia. He afterwards partially recovered, and on May 5th he was sensible enough to answer questions that were put to him; but in the following night he was attacked with another fit, of which he died in twelve hours. We found tubercles thickly scattered about the Sylvian arteries and in the adjacent parts of the pia mater, but without any lymph being present; both lungs contained many grey clusters. In that case it is probable that the tubercles had been formed more slowly than usual, for it was stated that a fit had occurred twenty-two days before the man's death, and that afterwards he was always drowsy and stupid.*

About a year later this very question was raised in a trial for murder. Harriet Staunton, the wife of one of the prisoners, had died in a state of neglect and emaciation, which led to suspicions that she had been starved or poisoned. The medical men who made the autopsy gave their opinion that death had been due to deprivation of food, and yet stated that they had discovered in the membranes of the brain bodies which they believed to be tubercles, but to which they attached no importance. What were the exact appearances must remain uncertain, for one report spoke of "small patches of rough, millet-seed-like deposit in the meshes of the pia mater," and another of "a small recent patch of tubercular deposit upon the arachnoid membrane on the upper part of one hemisphere, about the size of a fourpenny piece." The husband and three other persons were convicted of murder. But before the time fixed for their execution the leading pathologists of London addressed a memorial to the Home Secretary, and the lives of the prisoners were spared. If there really were tubercles in the meninges, the *immediate* cause of the woman's death was disease, and not starvation or chronic poison.

The reader may perhaps be disposed to doubt whether tubercles that are only discovered by the aid of the microscope are really so important. But just as in a case of concussion of the brain the presence of obvious ecchymoses of one or two convolutions (which cannot be regarded as themselves the cause of death) is nevertheless of the highest significance, so it would seem that the development of even the smallest tubercles in the pia mater is a sign of invisible changes in the cerebral tissues that are incompatible with the maintenance of life. For obviously meningitis cannot produce cerebral symptoms except by affecting the supply of blood to the brain.

Occasionally we can see obvious lesions in the brain as well as in the pia. Rindfleisch speaks of the superficial layer of the cortex—patches of which often remain sticking to the pia mater when it is stripped off—as infiltrated with leucocytes, and Huguenin says that inflammatory products may even be

* It ought to be added that he was a gouty subject, and had Bright's disease of the kidneys, so that one was obliged to take into consideration the question of uræmia.

found in the white substance of the hemisphere. Indeed, some one part of the brain is now and then found in a state of well-marked yellow or red softening. Five instances of this have occurred at Guy's Hospital, and others are mentioned by Rindfleisch and Huguenin. Sometimes the softened part has been the island of Reil on one side, sometimes the frontal or temporo-sphenoidal lobe. In one case Dr Goodhart could detect no granule-masses in the softened parts, but "the tissue was very fatty and granular, and the nerve-fibres seemed to have undergone destruction, scarcely any of them being visible."

Basal meningitis without tubercles.—In cases in which the symptoms and course have been altogether like those of tubercular meningitis, the membranes at the base of the brain and in the Sylvian fissures are sometimes found after death with well-marked signs of inflammation, but no evident tubercles. Six or seven cases of this kind are to be found in the records of Guy's Hospital, but in all of them, with one exception, the lungs (and often other viscera as well) contained miliary tubercles; in the one exceptional case the bronchial glands were caseous. A sufficiently careful microscopic examination might perhaps have cleared up the difficulty, but the pulmonary lesion was conclusive as to the real nature of the disease.

There is, however, a form of acute basal meningitis in which neither tubercles nor tubercular changes are to be found in any part of the body. This disease is described by Huguenin as *Leptomeningitis infantum*. He relates as a typical case that of a female child, aged eleven months, who died on the fourth day of an attack of measles, attended with convulsions and other cerebral symptoms. Flattening of the convolutions, injection of the choroid plexuses, distension of the ventricles, and softening of the central parts were the only obvious morbid appearances; but the microscope showed that leucocytes were abundantly present in the pia mater.

A striking instance occurred at Guy's Hospital in 1859, in the practice of the late Dr G. H. Barlow. A boy, aged nine and a half years, died after an illness of twelve days' duration, which began with intense headache and ran its course with convulsions, grinding of the teeth, strabismus, and coma. That the disease was tubercular meningitis was doubted by no one who saw the child, and when the skull was opened the brain looked flattened, as if by effusion; but, except that its tissue was soft and that there was a slight increase of fluid in the ventricles, no morbid changes were discovered. There were no tubercles in other organs.

Several similar cases have since been recorded at Guy's Hospital and elsewhere. Clinically, they are indistinguishable from tubercular meningitis of the base; but the prognosis is better, and their real pathology doubtful.

Ætiology.—The causes of tubercular meningitis are those of tubercular affections in general. Impure air, want of exercise, scanty food, and inherited predisposition, are its most important predisposing causes; it often attacks in succession several children of the same parents at about the same ages. When this is the case one is apt to suppose that there must be a special morbid susceptibility of the nervous centres, but it is to be borne in mind that, although clinically the cerebral symptoms mask all others, yet the disease is almost always a general tuberculosis. The exciting cause is the entrance of Koch's bacilli into the circulation.

Over-study, mental shocks, intoxication, or blows upon the head have each been supposed to give rise to tubercular meningitis. A policeman in one of our wards attributed his illness to over-fatigue in attending a review

in Hyde Park in June, 1860, but afterwards admitted that he had before complained of pain in the head. Three children have died in Guy's Hospital in whom the exciting cause of the same disease was attributed to a blow or fall upon the head.

All these "causes" are, there is little doubt, as imaginary as the pretended causes of syphilitic eruptions; but they are worth recording in order to warn us against accepting coincidences for causes in other diseases.

Sex and age.—Tubercular meningitis is much more frequent in males than in females. At Guy's Hospital the proportion has been as eighty to thirty-seven, and it does not seem to have varied very much at different periods of life, although Huguenin says that in children the preponderance of males is much more marked than in adults.

The relative frequency with which persons of different ages are attacked is not yet accurately known. There are no hospitals to which children and adults are brought in numbers corresponding with their ratios to the population as a whole; and until *post-mortem* examinations become universal, the Registrar-General's 'Reports' will fail to show the liability of grown persons to tubercular meningitis. It has always been known to be much less common in infants under two years than in older children, and we now see that this is due to their less chance of tubercular infection. Guersant met with one case in an infant only six weeks old.

Three cases have occurred at Guy's Hospital since 1854 in infants aged six months, ten months, and one year respectively. Of children between two and four years there have been fourteen cases; between five and seven and a half, nine cases; between eight and ten, twelve cases; between eleven and fifteen, eleven cases; between sixteen and twenty, sixteen cases —altogether sixty-five patients under twenty years old. Of adults between one-and-twenty and thirty there have been thirty-one cases; between thirty-one and forty, fourteen cases; between forty-one and fifty, eleven cases; between fifty-one and fifty-six, three cases—altogether fifty-nine patients above twenty years of age.

Clinical course.—The symptoms of tubercular meningitis are not essentially different in patients at different ages, but as the best writers have based their descriptions mainly upon observations of cases occurring at an early period of life, and as such cases present certain minor clinical peculiarities, we will begin with the disease as it is seen in *children*.

Premonitory stage.—In the first place, before any definite indications of cerebral mischief develop themselves, a general failure of health is often observed, which may last for several weeks or even for two or three months. The symptoms which are manifested during this period are termed "premonitory" or "prodromal." In the well-known work of Rilliet and Barthez on the diseases of children an admirable sketch is given, which has afforded materials for all subsequent writers. Probably these symptoms may be due to two different causes, sometimes to a scanty early formation of tubercles in the lungs or other organs, which is afterwards followed by a more abundant crop; sometimes to the slow progress of chronic caseation of the mesenteric or bronchial glands. Foremost among them is emaciation; the limbs waste and lose their roundness, the ribs and the muscles feel soft, are too easily felt and even seen, and the skin is lax and flabby. The cheeks often retain their plumpness of outline, so that the loss of flesh is first observed by the nurse who dresses and undresses the child; but the face becomes pale, the eyes are dull, and there is a want of animation in the

countenance. The appetite is diminished or capricious. The bowels are disordered, being generally constipated, but with intervals of diarrhœa; the evacuations may be pale and offensive. The disposition and the temper often become changed. The child is dull, apathetic, and slow in his movements; he is easily fatigued by lessons, and quickly tired of toys. Headache is sometimes present, or the child complains of being sleepy and tired and wanting to lie down. At night he is restless, lying with the eyes half closed, rousing at the slightest noise, and unable to sleep with a candle in the room; he often grinds his teeth, and starts or cries in his dreams. Whether fever is commonly present at this stage is doubtful, and slight pyrexia in a child might be caused by trifling gastric disorder.

Premonitory symptoms do not always occur, but Dr Gee says that among twenty-six cases collected by him there were only two in which they were not noticed. Their duration is very variable, sometimes not more than a fortnight but generally longer, and now and then even as much as four or six months. They may subside, and the child's health appear to improve, before the disease breaks out in a characteristic form.

Onset and early symptoms.—In marked contrast to the uncertain length of the prodroma, the subsequent course of the disease is seldom prolonged beyond twenty-one days from the occurrence of the invasion. An apparent exception to this rule is in cases of one or more tubercular tumours developing in the brain before the meningeal affection had begun.

The symptom that first excites alarm is most often repeated *vomiting*. Sometimes the child is sick only when it takes food, sometimes it brings up bilious matters even though it may have swallowed nothing. The sickness generally lasts for two or three days only, but it may go on for a week. If it once ceases for twenty-four hours it seldom returns. In some cases there is no vomiting for the first day or two, and occasionally it is altogether absent.

The initial symptom next in frequency is a *convulsion*, more or less completely epileptiform in character. In one instance mentioned by Dr Gee there was general rigidity which recurred several times; in another the attack took the form of temporary unconsciousness. In a single one of his twenty-five cases the invasion was marked neither by vomiting nor by convulsions, but by increase of the headache, drowsiness, and wasting which had existed during the premonitory stage.

Severe *headache* is now almost invariably present; the child keeps its hands pressed against the forehead, or may go on rubbing the scalp, first in one place, then in another. Trousseau lays stress on a peculiar inarticulate "hydrocephalic cry," which is sometimes heard from the very beginning of the disease, sometimes only towards the end; he describes it as a single, sharp, loud sound, like that of a person exposed to some sudden danger; it may be repeated every hour, or every five minutes, for several days together. We may often hear the hydrocephalic cry without hydrocephalus, but the symptom is marked and characteristic enough to deserve mention. For several days there may be no marked impairment of the intelligence; the child perhaps continues to talk rationally, but his answers may be rather slow, and his memory and power of perception somewhat impaired. He is apt to lie in a drowsy state, half asleep, with his eyes staring vacantly, or he may go on talking to himself, or repeating some phrase over and over again, or singing, whistling, and shouting.

The *pupils* are often sluggish, and very commonly one is larger than the

other. A tendency to squint is a frequent early symptom. Trousseau relates a case in which there was transient hemiopia; the child was sitting near a window when he called out, "Oh, mamma, look at that little boy, he has only half a blouse and half a face!"

Such are, as a rule, the symptoms of tubercular meningitis for perhaps eight days after its invasion. During this period there is more or less fever, the evening temperature rising perhaps to 102° or 103°, while in the mornings it may be 101° or 100°, or not above normal. The pulse may be a little quickened, or natural, or slower than natural; sometimes easily made more rapid by the slightest excitement. The frequency of the respirations is but little altered. Constipation of the bowels is almost always present, and the tongue is often but not always furred.

Later stage.—When about eight days have passed, the condition of the little patient undergoes a change, now and then almost sudden, but more often gradual. Its most striking feature is loss of consciousness; and the period which follows has been called the stage of cerebral pressure, in distinction from the preceding stage of cerebral irritation. The child now ceases to take notice of anything that goes on in the room. He often lies on one side, curled up with the knees drawn close to the abdomen, and the hands folded over the pudenda. Sometimes the head is drawn backwards, and the muscles of the nape of the neck may then be felt to be hard and rigid. He may keep grinding his teeth every few minutes, making a disagreeable jarring noise. The pupils now become dilated and insensible. One or more of the cranial nerves may be paralysed; the third, for instance, so that the eyelid drops; or more rarely the facial nerve. There may be loss of power in the limbs. Tickling the soles of both feet may cause only one leg to be drawn up. The evacuations are often passed into the bed.

The order in which the various symptoms make their appearance is uncertain; some of them may begin during the earlier period of the disease, before coma sets in. This is particularly the case with certain characteristic changes in the patient's aspect: a frown upon the brows, and deep lines around the nose and mouth; injection of one cheek, or of both. If the countenance is pale, it is liable to flush when the child is disturbed, or when anything is given it to drink. So, also, any part of the body which has been pressed upon shows a marked injection of its capillary blood-vessels. A particular instance of this was made into a leading symptom of tubercular meningitis by Trousseau, under the name of the *tache cérébrale*. He pointed out that if one draws one's finger-nail gently over the patient's thigh, or abdomen, or face, a bright red line is produced, and that this differs from the effect of an equally slight scratch in a healthy person by appearing earlier (within thirty seconds), by lasting longer (eight, ten, or fifteen minutes), and by being broader and of a deeper colour.

The *ophthalmoscope* may show ischæmia of the optic discs, or descending neuro-retinitis, or tubercles in the choroid. Dr Allbutt found some affection of the retina in twenty-nine out of thirty-eight cases.

Another symptom which may be observed in most cases at this period is retraction of the abdominal walls. Vomiting is generally absent, and the bowels may still remain obstinately constipated; but for some unknown reason the intestines no longer contain the usual quantity of gas; and the belly therefore becomes deeply hollowed, the rib-cartilages, the iliac crests, and the pubic symphysis appearing unduly prominent.

The *tongue* may now be red and dry, but it often still remains moist.

The *temperature* seldom rises above 101°; Dr Gee remarks that it may for days together remain at between 96° and 98°. Thus, if the case is advanced when the child is first brought to one, the disease may appear altogether non-febrile. The *pulse* during this period is generally infrequent, 60 or even 50 per minute; it is still apt to be irregular and unequal in force. A similar irregularity and inequality of the *respiration* are very commonly present; the child perhaps breathes rapidly three or four times in succession, and then the chest may remain motionless for some little time. Trousseau laid great stress on this symptom, and has recorded a case in which the breath was held for as long as fifty-seven seconds. Typical Cheyne-Stokes respiration is sometimes observed.

Final stage.—The "stage of pressure" may continue with but little alteration until it terminates in the patient's death, which is often preceded by a convulsive seizure. But in certain cases the symptoms during the last twenty-four or forty-eight hours are to some extent peculiar. One remarkable change is that there may be a brief return of consciousness for a short time before the end. Dr West relates how a girl, aged seven, who had been in a state of stupor for six days, and profoundly comatose for two days, became conscious, swallowed some drink, spoke sensibly, and said she knew her father; in the course of an hour and a half, however, she became worse again, and a little later she died. The pulse often becomes rapid during the last two or three days; and, as Dr Gee points out, the temperature may steadily rise until it is above 107°. But in some cases the beats of the heart remain infrequent up to the time of death; and the temperature even in the rectum may fall, until it is very low indeed. In one case, three days before the fatal termination, the thermometer registered 97·8° and 96°; next day the highest temperature was 96·2°, the lowest 93°; the day after they were 82·8° and 82·1° respectively; and on the day of death 80·5° and 79·4°. In other cases the face and limbs are livid and cold, and covered with a clammy sweat, while the thermometer shows that fever is still present. Towards the last a peculiar fœtid earthy smell is often perceptible; and it is strange that Rilliet and Barthez, after alluding to Whytt having mentioned this symptom, go on to say that they have not themselves recognised it.

Symptoms in adults.—The onset of tubercular meningitis in adults is seldom preceded by marked prodromal symptoms. It is often secondary to phthisis, and when this is the case the pulmonary affection is rightly regarded as the cause of any general failure of health that may have been noticed. Then, again, few grown-up persons are watched as carefully as children are by their parents and nurses; and in adult life loss of flesh may be due to so many other causes that tubercular meningitis is very unlikely to be thought of.*

The invasion is less often marked by vomiting in adults than in children; and an epileptiform seizure is still less frequent.

But although in adults the disease generally begins gradually and insidiously, yet we have had at Guy's Hospital more than one case in which the sudden occurrence of convulsions has been the precursor of a fatal

* I must state it as my impression that most of the patients whom I have seen have been fairly well nourished at the time of death. I have no recollection of having ever observed a very marked degree of wasting, unless when it was obviously referable to some co-existing visceral disease; and in the case of Harriet Staunton, already referred to at p. 637, I should have been reluctant to regard the extreme emaciation, which must have been going on for several weeks, as dependent upon the presence of meningeal tubercles.—C. H. F.

termination within a day or two, and in which an autopsy has shown that the disease was tubercular meningitis. It is not at all uncommon for death to take place after an illness of twenty-four or forty-eight hours only. In 1868 a man, aged thirty-two, a patient of Dr Wilks, died within two days of having been about his business as a draper; on admission he was so restless that he had to be held down in bed, but he quickly became comatose. In another case there was violent delirium two days before death.

In some cases of tubercular meningitis in adults the first symptom is well-marked *local paralysis*, which is extremely rare in children. In 1871 a woman, discharged from a surgical ward with advanced phthisis, came the same morning to seek readmission as a medical patient. No symptoms of cerebral disease had been observed, but she had paralysis of the left facial nerve, which must have developed within a few hours. She was admitted into the Clinical Ward; and was intelligent enough to be able to say that she could not hear the ticking of a watch with the left ear. But she soon became drowsy, then comatose, and at the end of six days she died. At the autopsy no special affection of the facial nerve could be found either in the petrous bone or elsewhere.*

Lastly, tubercular meningitis in adults may have *hemiplegia* for its earliest, and even for its principal, symptom. Three instances of this have been observed at Guy's Hospital within the last few years. One patient was a man aged thirty-three, who was admitted on account of an abdominal tumour which proved afterwards to be a tuberculous omentum. Some days before his death he was attacked with loss of power in the left arm and leg; he was sensible to the last. In the other two patients the right limbs were affected, and, as the superficial seat of the lesion might have led one to anticipate, the paralysis was accompanied by well-marked aphasia. One of them was a woman, aged twenty-six, who came under Dr Wilks's care in 1867; until the real nature of the affection was revealed at the autopsy there was not the slightest suspicion of its being due to anything but disease of the Sylvian artery. The other, also a woman, aged forty-one, had been attending as an out-patient for phthisis, when she was seized with right hemiplegia and loss of speech; afterwards she became semi-delirious and her paralysis changed sides. In none of these three cases was any well-marked change found in Broca's convolution or in the adjacent parts of the brain; but in a boy aged nine, in whom right hemiplegia and aphasia were combined with the more ordinary symptoms of tubercular meningitis, there was reported red softening of the left third frontal, and of the inner ends of the two left ascending (or central) gyri. Huguenin relates three instances in which paralysis of the right limbs and loss of speech were the chief symptoms; in two of them many tubercles were present in the left Sylvian fissure, but none in the opposite one, and in the third case the pia mater in the left fissure was more thickened than anywhere else. In one of the cases in which there was red softening of the left island of Reil and Broca's

* Huguenin has attempted to trace the affections of special cranial nerves occurring in tubercular meningitis to definite local changes. In one instance, in which the face was paralysed, he found the portio dura thinned, of a yellow colour, and covered with a large quantity of pus; cellular elements were present in numbers in the nerve-sheath, but the fibres appeared to be intact. In another similar case, however, no change could be found in the nerve. In one instance, in which there had been convergent strabismus, the abducens was greatly diseased, diffuse suppuration having occurred between its fibres. Similar appearances were twice discovered in the third nerve, when the muscles supplied by it had been paralysed during life; but in some other cases, in which the same symptoms had been incompletely developed, the nerve seemed to be normal.

convolution, the first symptom after headache was speechlessness, but this lasted only about seven minutes, and two days afterwards the patient (a man aged fifty) was able to go to business as usual. One can only suppose that the aphasia was due to functional disturbance of Broca's region.

The observations made at Guy's Hospital seem to show that, when there are no inflammatory changes in addition to the tubercles, there is usually no persistent coma. Violent delirium is sometimes associated with the presence of numerous tubercles between the convolutions of the upper surface of the brain. Choked discs are probably an indication of a general increase of pressure within the cranial cavity, whereas neuro-retinitis points more definitely to inflammation at the base of the brain, in the neighbourhood of the optic tracts or nerves. The extension of meningitis to the spinal canal probably gives rise to rigidity of the muscles of the neck, which in children at any rate is very common; for this is one of the chief symptoms of an epidemic form of meningitis which affects the spinal as well as the cerebral membranes; and sometimes the occurrence of painful cramps or spasms in the limbs may be attributed to the same cause.

Diagnosis.—This may be very easy or very difficult, either in children or adults. During the first few days of a case which is to last two or three weeks one is often unable to speak positively, but there is seldom much uncertainty when its fatal character is once fully developed.

All writers lay stress on the importance of distinguishing it from *enteric fever*, and the fact is indisputable that many cases, which for a week or ten days are supposed to be examples of that disease, afterwards become attended with such well-marked cerebral symptoms that the diagnosis is forthwith altered to that of tubercular meningitis. Thus Rilliet and Barthez describe a special form as having a *début typhoide*. But although to the clinical observer the meningeal affection masks all the other features of the case, yet the pathologist almost always finds it to be only a part of general miliary tuberculosis, which in reality constituted the patient's illness from its commencement, and to which the early febrile symptoms were due. In our reports at Guy's Hospital two instances are recorded in which the first diagnosis was that of fever, and in which tubercles were found in the meninges and nowhere else. Sometimes the opposite error is committed, enteric fever being attended with strabismus and irregularity of pupils, vomiting, and constipation, as well as with headache, delirium, and coma, so as to be taken for meningitis. The *tache cérébrale* of Trousseau affords little help in doubtful cases.

The clinical value of ophthalmoscopic changes in the optic discs is still uncertain. A normal state of the retinæ is no proof of the absence of tubercular meningitis, and the positive significance of ischæmia, or even of retinitis, is not yet established. One appearance, indeed, is conclusive, namely, the presence of tubercles in the choroid. It is true that they belong, not to the meningeal affection itself, but rather to general acute tuberculosis, but this fact in no degree diminishes their diagnostic importance; for whenever there are tubercles in the membranes the case always assumes clinically the aspect of a cerebral disease, even though they may be far more numerous elsewhere. In fact, in all cases of suspected tubercular meningitis one should carefully search the lungs for the very slight indications of acute tuberculosis which they sometimes yield, and examine the testes, the lymphatic glands, and other organs, for chronic lesions of the same nature.

In a patient fifty years of age who was brought comatose into John

Ward in April, 1875, the writer found evidence of phthisis, and this led to a correct diagnosis.

A condition that formerly was often mistaken for tubercular meningitis, is one, not infrequent among young children, which has been rendered classical by the descriptions given of it by Marshall Hall (1825), Abercrombie (1828), and Gooch (1829). The first of these writers called it "*the hydrocephaloid disease*;" Sir Thomas Watson gave it the name of "spurious hydrocephalus;" and Dr Gooch stated that he had "invariably found it attributed to and treated as congestion or inflammation of the brain." At the present day a skilled practitioner is not likely to fall into the error of diagnosis which sixty years ago was so frequent; and at any rate the mistake is not now likely to be attended with any serious results. Among the chief causes of the affection was one to which children are no longer liable, namely, venesection. A case related by Marshall Hall is that of a girl under three years old, to whom sixteen leeches had been applied for an attack of influenza; and he states that all his patients were in a state of exhaustion before they were attacked by the cerebral symptoms; many of them had had protracted diarrhœa after weaning. On the other hand, Dr Gooch says that in most of his cases there had been no previous illness; but perhaps he scarcely appreciated the gradual effects of insufficient or improper food.

The child's aspect is characteristic; it lies on its nurse's lap, unwilling to raise its head, drowsy or even comatose, with sunken, half-closed eyes, dilated insensible pupils, irregular and sighing respiration. The face is pale, and the skin cold. Dr Gooch, indeed, speaks of a slight and transient flush as being sometimes present, and Dr Hall of an early stage in which the little patient is irritable, restless, feverish; but such symptoms very seldom, if ever, last long enough to mislead a careful observer into the diagnosis of meningitis. Depression of the fontanelle is an important symptom of exhaustion in children, although it seems formerly to have escaped notice. The proper treatment is to give ammonia and brandy, but, above all, to take care that suitable food is supplied. For an infant recently weaned a wet-nurse should generally be procured; and a return to the breast is often advisable, even when the child is some months old, and has long been fed with the bottle. At least it ought to have asses' milk, or goats' milk, if cows' milk should appear not to be readily digested. To prescribe leeches and calomel would probably be fatal.

At Guy's Hospital we have had cases, supposed during life to be examples of *mania*, *delirium tremens*, or *epilepsy*, in which the disease has turned out to be tubercular meningitis. Huguenin remarks upon the possibility of mistaking this disease for *uræmia*, when a chronic renal affection, in reality tuberculous, is attributed to morbus Brightii. A curious case occurred some years ago at Guy's Hospital, that of a painter, who came saying that he had "lead colic," and that his bowels had not been open for a fortnight. In the evening after his admission he had convulsions and became insensible, and on the next day he died. There was caseous disease of two of the lower dorsal vertebræ, with a large abscess in front of the spine; and the membranes of the brain and cord showed the characteristic appearance of tubercular meningitis. The same disease has been found on *post-mortem* examination in two cases of boys admitted into the surgical wards for symptoms supposed due to vesical calculi; no cause could be discovered for the irritability of the bladder from which they had been suffering before any obvious signs of cerebral mischief appeared. A very similar case

occurred in a woman who was taken into a medical ward for vesical symptoms; but in addition to tuberculosis of the pia mater there was a tumour in the spinal cord.

The diagnosis between tubercular meningitis and other *organic affections of the brain*, particularly abscess and tumour, is often difficult and sometimes impossible. Probably not a few cases in England have been recorded as examples of sporadic *cerebro-spinal fever*, which have really been tubercular. It is of practical importance to remember the possibility that syphilis may be the cause of the most varied cerebral symptoms.

In adults, however, the most serious error of all is to mistake tubercular meningitis for *hysteria*. Many such mistakes have occurred, and sometimes with lamentable results. A woman, aged twenty-five, had long been "odd in her mind and scarcely to be trusted;" she was attending as an out-patient, with hysterical symptoms, when she sought admission to Guy's Hospital, and died three days later. There were several yellow tubercles in the brain, as well as the usual appearances of tubercular meningitis.

Prognosis.—Tubercular meningitis is one of the most fatal of all diseases. Rilliet has recorded a single instance of recovery, in which the child died five and a half years afterwards of a second attack, and at the autopsy the remains of the former disease at the base of the brain were clearly recognised; and one similar case is mentioned by Trousseau. The late Dr Carrington recorded a third and a most conclusive case. But such instances are almost without parallel.

It is, however, by no means very rare for recovery to take place in cases in which tubercular meningitis had been diagnosed more or less positively, and for the nature of the disease to remain uncertain, as it must necessarily remain in such cases, unless an accident should lead to an autopsy being made at a future time. How closely a case which terminates in recovery may resemble tubercular meningitis is strikingly illustrated by a clinical history which we owe to Dr West. A child, aged three years and a half, a member of a phthisical family, was attacked by a disease which ran the ordinary course of acute hydrocephalus, unchecked by the customary treatment. Convulsions took place, coma succeeded them, deglutition was very difficult, the pupils were dilated and almost motionless, the pulse was very feeble and very frequent, and everything portended a speedy death. A younger brother had died a year before of the same disease. Food was still given, as the power of swallowing was not entirely lost, and ammonia and ether were administered, and after a time quinine. For days the child remained unconscious, but at length she began to raise her hands to steady the cup that was put to her lips. Next she recovered her sight, after some weeks she became able to speak, and after many months she began to walk with a tottering step. Three years afterwards, although her intellect was not defective, she still had a vacant smile, and had never regained flesh, nor recovered the look of health; her gait also remained unsteady. Whatever the real nature of this case may have been, one cannot be wrong in learning from it not to make an absolutely fatal prognosis in what appears to be a case of tubercular meningitis. However confident we may be in our diagnosis, and however threatening may be the symptoms, our opinion should be given with some reserve.

The *treatment* of tubercular meningitis will be discussed when the other forms of inflammation of the pia mater have been described.

ACUTE SIMPLE MENINGITIS.—Some modern writers describe several forms of acute non-tuberculous inflammation of the membranes of the brain under distinct names, according as the convexity or the base is affected. Undoubtedly a case in which the whole surface of the brain is covered with a thick layer of pus is attended with much more violent symptoms and destroys life far more quickly than one which is limited to a particular region, and in which only a small quantity of lymph is effused. But no complete division into separate categories is possible.

Anatomy.—When the most intense degree of inflammation has been present, one finds, on turning back the dura mater, that the cerebral convolutions are completely hidden by a green purulent material. This looks as if it were spread out over the hemisphere in the *subdural* space; but by scraping the arachnoid surface one generally discovers that little, if any, of it is really free. Moxon says that even when some of the exudation had appeared to come off upon the edge of the scalpel, he often found only epithelium and detritus on examining it with the microscope. Sometimes, however, a considerable quantity of pus is subdural, but only when the disease was due to extension from without. The converse, however, is very far from being true; namely, that meningitis is always attended with exudation into the "arachnoid cavity," when it is set up by such causes as caries of the petrous bone or necrosis of the calvaria. For in the great majority of these cases no subdural pus is found; and whenever it is widely diffused over the hemispheres it is also abundant in the meshes of the pia mater.

The pia mater may be swollen to many times its normal thickness, appearing either soft, green, and gelatinous, or firm yellow and felt-like, according to the consistence of the exudation infiltrated into its substance. And from such a condition there may be every gradation, down to a point at which only slight traces of pus can be discovered along some of the principal vessels, or at the base, or in one Sylvian fissure, or on a single lobe of the cerebellum.

In some of the more severe cases the convolutions themselves are softened. When the pia mater is stripped off it carries with it portions of the cerebral tissue, leaving a ragged surface behind. Huguenin says that numerous leucocytes may be found throughout all the layers of the cortex, and that suppuration of the brain-substance may actually reach such a point as to give rise to a diffused yellow-grey maceration visible to the naked eye. The vessels often contain but little blood in consequence of the increased pressure which precedes death. The ventricles may either be empty or contain a turbid liquid, or even pus. The choroid plexuses are sometimes infiltrated with inflammatory products.

Some of the sinuses in the dura mater are now and then found plugged with *ante-mortem* clots, even when the meningitis is not secondary to any disease of the bones which could itself have set up the thrombosis by extension. In a little girl aged three, for example, who died in Guy's Hospital, and in whom both hemispheres were covered with a thick layer of yellow lymph, each lateral sinus, but especially the left, was filled with a greenish softening material.

How often a primary acute meningitis of the brain spreads to the membranes of the spinal cord it is impossible to say. In the majority of recorded cases the vertebral canal has not been opened, but we have had at Guy's Hospital at least eleven cases in which inflammatory products have been found in greater or less quantity beneath the spinal arachnoid. In

none of them was there any reason to believe that the disease was of epidemic origin; in four it was directly caused by fracture of the skull or severe injury to the brain, or arose by extension of mischief from the cranial bones.

Ætiology.—The causes of simple acute meningitis are various. Most frequent among them are *injuries to the head.* These generally come under the notice of the surgeon, but the physician must remember that the disease sometimes follows a blow or fall which may not have produced any external bruise, and about which the patient may say nothing, particularly if he should have been intoxicated at the time. Some years ago a man was admitted into Guy's Hospital for a fractured thigh, caused by his having fallen into a cellar while drunk. He died at the end of five weeks, having been delirious at the time. He was believed to have delirium tremens; nothing was known of any injury to the head; he had been able to get out of bed and stand upright. At the autopsy it was found that there was general acute meningitis affecting the base as well as the surface; a small part of one parietal bone, over an area an inch in diameter, was of a greenish colour, and its diploë was reddened. Both the periosteum and the dura mater seemed quite healthy, but it was thought probable that the bone had been injured at the time of the accident. Another common cause of meningitis is the extension of inflammation from *chronic disease of the skull.* Syphilitic caries or necrosis of the calvaria sometimes kills in that way, and such a result may be altogether unexpected until a very short time before his death.

Six cases of meningitis due to *affections of the ear* have been observed at Guy's Hospital within the last few years (1880), a smaller number than that of the cases in which cerebral abscesses were due to the same cause.* One patient, a man aged twenty-two, was said to have had sunstroke seven days before being attacked, and another man, aged twenty, had been struck on the head with a bolster immediately before dangerous cerebral symptoms set in. In each instance it was clear that the inflammation started from a diseased temporal bone, but there was a question whether an independent "exciting" cause was not in operation (see a case of the writer's, 'Path. Trans.,' vol. xxxix, p. 228). In the case of a woman, aged twenty-seven, no history could be obtained; and no cause for the meningitis of which she died was discoverable; so the ears were specially examined by the late Mr Hinton, and he found pus in the labyrinth on one side. To this accordingly the disease was attributed, but it must be remembered that in epidemic cerebro-spinal fever inflammation often spreads to the ears from the membranes, and there seems to be no reason why the same thing should not occur in the simple form of the disease.

Numerous other local affections may be mentioned as occasionally giving rise to meningitis. *Local pyæmia* from carbuncle of the face may cause it, as in a case which the writer saw many years ago in a girl about seventeen. In two cases an epithelioma, commencing in the lip, extended with ulceration along the pterygoid region until it passed through the foramen ovale into the interior of the skull. In another, a little girl had necrosis of the upper jaw after measles, and the cavernous sinus was full of a dirty-brown fluid. Or the disease may be set up by suppuration of the eyeball, travelling, in all probability, along the sheath of the optic nerve. Trousseau relates a case

* Dr Pitt also has since found that meningitis without abscess or thrombosis of a sinus is the least frequent of the results of disease of the ear (1890).

in which its starting-point was a chronic affection of the first two cervical vertebræ.

Next in frequency to the cases of meningitis that are traceable to local causes come those which are secondary to some other acute disease. More careful research may hereafter show that these also have a *local* starting-point in some lesion affecting the cerebral vessels.

At Guy's Hospital we have had two cases in which inflammation of the pia mater accompanied an attack of *erysipelas* of the scalp; in one it is noted that the calvaria was discoloured yellow. In four instances it appeared to be part of general *pyæmia;* once there was a grey patch of cerebritis reaching the surface; once pericarditis also was present, so that one might regard the disease as specially attacking the serous membranes if the arachnoid could still be called by that name; once the meningitis was the only evidence of blood-poisoning, but such seemed to be the most probable explanation of its occurrence, as it came on six days after an operation for imperforate anus in a child a year old; once it was associated with an abscess in the lung, and with suppuration in the mediastinal connective tissue and in the substance of one leg, there being, however, no obvious primary lesion. In a single case inflammation of the cerebral membranes was believed to be a complication of *typhus;* no affection of the vessels in the pia mater was discovered, but the spleen contained infarcts, and there was thrombosis of the renal veins. Four times it seemed to be secondary to acute *pneumonia* or pleurisy: all but one of these cases, however, presented peculiar features. One occurred in a man, aged twenty-two, who had been in the hospital six weeks for pleuro-pneumonia, and was convalescent and able to go into the grounds when he was again attacked with dyspnœa and high fever, and died in three days; the spinal membranes, as well as those of the brain, were inflamed. Another was in a woman, aged twenty-seven, who had been ill for a week with pleurisy and then was attacked with an acute diphtheritic affection of the fauces, and died a day later, having been very restless towards the last and having one pupil wider than the other; in her, also, the affection was cerebro-spinal. The third case was that of a man, aged twenty, who had acute meningitis involving both hemispheres of the brain, and pleuro-pneumonia of the lower lobe of the left lung; he was suffering from gonorrhœa, and Dr Wilks was inclined to regard this as the cause of his fatal illness, but it was further said that he had had a blow on the head a few days before he was attacked. In the remaining case the patient was a temperate man, aged fifty-seven, who died, after sixteen days' illness, of acute pleuro-pneumonia affecting the left lower lobe; no cerebral symptoms appear to have been observed beyond delirium before death. There was much recent lymph, both at the base of the brain and on the vertex. The only other morbid conditions that were discovered were chronic renal disease (apparently in moderate degree) and hypertrophy of the heart.

Huguenin says that at Zürich inflammation of the cerebral membranes is an exceedingly frequent complication of acute *pneumonia.* He quotes Chvostek as having found it four times in 220 cases in Vienna, and adds that in Zürich the percentage is higher.

Dr Moxon laid special stress on the fact that *syphilis* sometimes seems to be the cause of an acute simple meningitis, and the author found five cases of this kind in our records, in addition to those in which inflammation of the membranes was set up by disease of the calvaria. Once a gumma was discovered in the brain-substance. In no instance was any disease noticed

in the cerebral arteries, but it seems very probable that such a lesion may hereafter be discovered in similar cases. In 1871 a man, already in the hospital for disease of the aortic valves with regurgitation, died after two days' illness of cerebro-spinal meningitis; no embolism was detected, but the spleen contained infarcts. In 1874 a woman, aged forty-eight, who had been admitted for chronic jaundice caused by biliary calculi, was attacked by a fatal inflammation of the cerebral membranes; this, however, was doubtless consequent upon ulcerative endocarditis of the aortic valves, which was discovered at the autopsy. It is remarkable that our records do not show evidence that Bright's disease is a cause of meningitis.

There remain a few cases in which meningitis can be traced to none of the causes mentioned, and must be called *idiopathic*. In our records at Guy's Hospital there are at least nine cases of this kind. In three of them pus or lymph was spread out in large quantities over the whole surface of the brain, equally over the hemispheres and at the base; in three the amount at the base was much less than upon the convexity: in one the latter region was alone affected, the material being in this instance lymph. Once the under surface of the brain and the subarachnoid space of the spinal cord were all bathed in pus, there being but little upon the hemispheres. In the two remaining cases the distribution of the inflammatory products was the same as in ordinary examples of tubercular meningitis. In every instance the cause of the disease remained a mystery, but sometimes meningitis of the convexity is set up by the action of the sun's rays upon the head. Huguenin speaks of labourers who have been attacked while working bare-headed in the fields, and he gives full details of the case of a sailor who fell ill the day after he had been rowing without anything upon his head in the hottest weather of July, and who died in five days. Another case related by the same writer is that of a student who was foolish enough to spend three hours, from 1 to 4 p.m., during a hot summer's afternoon, paddling about the Lake of Zürich on a floating board. All the exposed parts of his body were severely sunburnt. At 6 p.m. he was seized with headache, and an hour later with shivering, and all the symptoms of meningitis rapidly developed themselves; his illness, however, terminated in recovery. Guersant met with a similar instance, which ended fatally, and was verified by an autopsy, in an infant aged six months, whose cradle had been left in the sunshine in the middle of a garden. Rilliet and Barthez mention the case of a child who was attacked after reading a book in strong sunlight.

Course.—The symptoms of acute simple meningitis bear a general resemblance to those of the tubercular affection; in the typical forms of both there is a stage of "irritation," which is succeeded by a stage of "pressure." But the more severe cases of the former present the peculiarity that each of the two periods, although marked by the most characteristic symptoms, may yet terminate within two or three days, or even less.

Primary meningitis commonly begins quite suddenly; it has no prodroma. The patient, if an adult, may be seized with a rigor; in children this is less common. Headache is generally present from the first; it may either be referred to the forehead, or affect all parts alike. There may be exacerbations from time to time, in which piercing cries are uttered; the agony appears to be altogether intolerable. Giddiness is frequently an early symptom; the ground seems to give way beneath the feet, and the legs may feel so weak that to stand upright is almost impossible. Vomiting, perhaps,

occurs once or oftener. There is an extreme irritability to light and sound. The eyes are brilliant and injected, the face is flushed, the head is hot, the carotids are felt to throb violently. The temperature rises, and may reach 104° by the third day; there may be great complaint of thirst. The pulse is quickened as a rule, but this is not always the case. Epileptiform convulsions are not uncommon, and sometimes mark the commencement of the disease. The back of the neck is often rigid, so that the patient seems to bore his head into the pillow. Sometimes his limbs are stiff. He generally lies coiled up in bed, anxiously avoiding notice, and most unwilling to be disturbed in any way. His mind may for a time be perfectly clear, but afterwards he becomes delirious. In some cases there is violent maniacal excitement from the very first. Sleep is altogether wanting, or very broken and disturbed. The pupils are, as a rule, contracted; the ophthalmoscope may show either ischæmia or neuro-retinitis.

The second stage of the disease is characterised by stupor, which more or less quickly passes into coma. The pupils are sluggish, or even dilated and insensible; they are often unequal in size. There may be loss of power in the limbs of one side with or without a similar affection of the corresponding half of the face. Sometimes the patient squints; but even when the base is involved one can seldom make out a definite paralysis of any of the cranial nerves; they of course remain unaffected when the inflammation is limited to the convexity of the brain. Epileptiform convulsions may return again and again until one of them proves fatal, or they may be altogether absent, or, again, there may be attacks of spasm confined to certain muscles or to one arm and one leg. The temperature generally remains high, ranging from 102° upwards, but the face is now pale, and the extremities may be cold to the touch and bathed in a profuse sweat. Towards the last the evacuations are passed involuntarily.

The duration of non-tuberculous meningitis varies with its intensity. Those cases in which the whole surface of the brain, including the convexity, is inflamed scarcely ever last more than a week, and generally terminate within three or four days. When the base alone is affected the patient sometimes lives as long as in the tubercular form of the disease. But this is by no means always the case; he may die in forty-eight hours, and the only discoverable morbid change may be on the under surface of the brain. In such cases, however, there is no successive development of the symptoms in regular order. Sometimes the patient is attacked with epileptiform convulsions and becomes quickly insensible, or he may be violently delirious. In certain cases loss of spirits is the earliest symptom, as was noticed long ago by Abercrombie. There may be little or no pain in the head, and thus the real nature of the disease may be altogether overlooked.

Diagnosis.—Non-tubercular inflammation of the meninges may be as difficult to recognise, as we have seen tubercular meningitis to be; but the diseases most likely to lead one into error are not quite the same. When it is impossible to make out the presence of any of the recognised causes of the affection, and when the symptoms are obscure, one may be unable to distinguish it from alcoholism, mania, or epilepsy. On the other hand, when the patient is known to be suffering from acute pneumonia or erysipelas it may be very hard to determine whether there is more than the ordinary symptomatic delirium. Cases in which alarming indications of cerebral disturbance are traceable to otorrhœa seem to be peculiarly liable to be wrongly interpreted. In 1877 the

author made an autopsy in the case of a patient of Dr Frederick Taylor's, who had died with what appeared to be clear symptoms of meningitis secondary to disease of the ear, including convergent strabismus, a swollen œdematous condition of both optic discs, delirium, and coma. The only sign of any disease of the encephalon was a blackened state of the arachnoid over a small part of one lobe of the cerebellum, but there was a putrid thrombosis of the lateral sinus and jugular vein, and this had set up numerous pyæmic abscesses in the lungs. In the 'Med. Times and Gazette' for 1877 will be found a precisely similar case, under Dr Wilson Fox, in which the patient had all her limbs flexed, and suffered from headache, photophobia, and hyperæsthesia of the surface, but in which the brain and its membranes were perfectly healthy. It would therefore appear that pyæmia dependent upon thrombosis of a lateral sinus is capable of simulating meningitis. The point is of the more importance in that the former disease seems not to be always fatal; at least this appears to be the most probable interpretation of two cases recorded by Dr Andrew in the 'Med. Times and Gazette' for 1875. One was that of a youth, aged sixteen, who had had a discharge from the ear, and who became drowsy and heavy, with frontal headache, giddiness, sickness, and blurring and œdema of the optic discs. The other occurred in a girl, aged nine, who had also had ear disease, and who was attacked with pain in the head, vomiting, and delirium, so that she screamed and started in her sleep. Meningitis was diagnosed, but each patient recovered after an illness of some weeks' duration, in the course of which there was distinct evidence of pyæmia, one of them having pneumonia, the other having an abscess in the thigh.

Lastly, there is always an element of uncertainty in regard to the diagnosis of those cases in which the typical symptoms of meningitis develop themselves in regular order, and with such rapidity as to threaten a fatal termination within three or four days, or even still earlier. The author recorded more than one instance of this kind, in which the gravest prognosis was given, but in which complete recovery took place. One case was that of a young lady, the daughter of a medical man. Her education had been rather neglected during childhood, and she had been for some weeks straining all her powers to keep pace with her schoolfellows in her studies. Her symptoms appeared to point clearly to the presence of meningitis; yet the attack passed off, and she recovered her previous good health.

Prognosis.—The question as to the possibility of recovery from acute simple meningitis is still more definitely raised by certain cases which come under the notice of ophthalmic or of aural surgeons. In 1866 Mr Hutchinson recorded in the 'Ophthalmic Hospital Reports' a series of cases of children who were brought to him for blindness, which he found to be due to optic neuritis, and nearly all of whom had had a severe illness, attended with delirium and other cerebral symptoms, and supposed to be fever. Dr Allbutt suggests that the disease was really meningitis. This observer also states that he has seen several instances in which a condition of defective mental development or idiocy, associated with atrophy of the optic discs, has in all probability been referable to a long past inflammation of the cerebral membranes.

Certain cases in which permanent deafness has resulted from an acute illness have been interpreted in a very different way by Voltolini (who first drew attention to them in 1867) as well as by some other writers. According

to Brunner (of Zürich) the affection in question commonly sets in suddenly; a child suffers from fever; he may vomit; his head is hot; he becomes excited and delirious, tossing about in bed and screaming violently; within the first twenty-four hours he becomes partially unconscious, and after two to four days passes into a state of coma. At the end of another period of two to four days, however, consciousness returns; but when the child first tries to walk he is found to stagger. He quickly becomes deaf and, as a consequence, remains dumb for the rest of his life. Voltolini's theory is that the disease in such cases is an acute inflammation of the labyrinth; the cerebral symptoms (as in Ménière's disease) being caused in some way by the aural affection. Direct evidence from dissection after death is as yet wanting; but, as Brunner remarks, the fact that the deafness is constantly bilateral is opposed to Voltolini's interpretation. He thinks that there may be some morbid change on the floor of the fourth ventricle, implicating the *striæ acusticæ*.

Voltolini's cases and those of Mr Hutchinson and Dr Allbutt must be taken together with other cases in which recovery takes place after an illness resembling meningitis, but without either deafness or blindness or idiocy resulting.

One difficulty in deciding on the presence of meningitis in such cases is the circumstance that one scarcely ever finds in the deadhouse adhesions of the membranes at the base of the brain or other clear evidences of a former meningitis. It has, however, been shown that in epidemic meningitis recovery is not infrequent, and that the disease often leaves behind it deafness or blindness; in several cases the remains of inflammatory exudation have been discovered when the disease has run into chronic hydrocephalus, which has proved fatal a few months later.

The important point, the practical one, is that cases which appear to be well-marked examples of inflammation of the membranes of the brain do not always terminate fatally.

Thus in a case of meningitis one should never quite lose heart; scarcely any is so hopeless as to justify one's abandoning it altogether, particularly if the patient is a child.

EPIDEMIC MENINGITIS.*—From the earliest years of the present century there have been recorded from time to time, in various parts of the Northern Hemisphere, epidemics of a disease characterised anatomically by inflammation of the membranes of the brain and cord, and clinically by fever, various eruptions, and a number of cerebral and spinal symptoms, especially rigidity of the neck, or of the whole vertebral column. So striking is the symptom last mentioned that in Germany it has given to the affection the popular names of "Genickkrampf" and "Nackenstarre." In medical works it has been called "epidemic cerebro-spinal meningitis." But the epithet "cerebro-spinal" suggests the incorrect notion that an extension of the inflammation to the membranes of the cord distinguishes it from tubercular meningitis.

History.—The first well-ascertained epidemic of this disease seems to have been in 1805 at Geneva. In 1806 it appeared in the United States and continued to prevail there for ten years. During this time, and indeed throughout the past half of the century, it was observed in several towns

* *Synonyms.*—Cerebro-spinal meningitis—Cerebro-spinal fever—Meningitis cerebro-spinalis epidemica.

of France and Italy, in Algeria, Spain, Denmark, &c. In 1854 and for seven years afterwards it raged in Sweden, and destroyed more than 4000 persons. From 1861 to 1864 it showed itself in various parts of the United States. In 1863 it broke out in Germany; the north-eastern provinces of Prussia were the first to suffer; but within the next year or two it appeared in Erlangen, in Nuremberg, and in the country districts of Franconia. From that time it has never ceased to show itself at intervals of a few months or longer, now in one part of the German Empire, now in another.

The British islands have hitherto been remarkably free from this disease. In 1846 it appeared in many of the workhouses of Ireland; and in 1866—1868 a very fatal type of it prevailed in Dublin, and to some extent in other parts of the country. Scotland has not been visited by this disorder; and in England only a few isolated epidemics have been observed in certain provincial towns and villages.

A few cases have from time to time been recorded as sporadic examples by writers who seem to have thought that the fact that a meningitis was cerebro-spinal was of itself sufficient to justify a presumption that it was related to the epidemic disease. But all forms of inflammation of the base of the brain are apt to extend to the cord, and the symptoms observed in the cases in question are far from conclusive.

Anatomy.—The morbid anatomy of epidemic meningitis has little to distinguish it from sporadic basal meningitis. Pus and lymph are found both at the base and on the convexity of the brain, especially between the pons and the chiasma, along the large vessels, and in the various depressions and furrows on its surface. It rarely happens that the hemispheres are uniformly covered by it. In the spinal canal the exudation is generally most abundant at the lower part, and on the posterior surface of the cord, having perhaps accumulated there by gravitation. The ventricles of the brain mostly contain turbid serum or pus; and the choroid plexuses and ependyma may be coated with puriform lymph.

Punctiform hæmorrhage or small spots of softening may be seen in the cerebral substance; or it may be œdematous. The cord presents similar changes but less marked. In one case Fronmüller is said to have found the central canal dilated and full of pus.

Among the appearances presented by other organs are congestion and œdema of the lungs, engorgement of the liver and spleen without much enlargement of the latter, a relaxed state of the heart, congestion of the kidneys with fatty epithelium and fibrinous casts in the tubes, and a granular degeneration of the fibres of the voluntary muscles, especially of those which lie along the spine. Rigor mortis is said to be of long duration. The cadaveric stainings of the surface appear early, and are not always limited to the dependent parts of the body.

The pericardium and the pleuræ are sometimes found ecchymosed, and occasionally lined with puriform lymph. Von Ziemssen once saw the large intestine inflamed as in dysentery. The joints often contain pus, and sometimes there are scattered abscesses among the muscles. All these complications must be regarded as dependent on secondary pyæmia.

Course and symptoms.—As a rule cerebro-spinal fever sets in suddenly; the patient may be at work, or (if a child) at play or at school, when he is seized with shivering and violent pain in the head, and feels so ill that he is obliged to go to bed at once. But sometimes—among Ziemssen's cases in

five out of forty-three—there are slight premonitory symptoms, consisting of headache, malaise, nausea, loss of appetite, and wandering pains. In several instances these passed off, and there was an interval, in which the patient felt perfectly well, before the disease began with its usual violence.

Vomiting is almost always an early symptom, being repeated whenever an attempt is made to sit up. After a day or two it generally ceases, but the headache mostly continues throughout the whole course of the disease, although it may sometimes subside for a time. It varies in character and in seat, being sometimes frontal, sometimes occipital, sometimes diffused over the whole of the head. Giddiness is often present with it. In cases of moderate severity the patient lies in a state of stupor, tossing restlessly about, but rousing when spoken to and trying to answer. He is often very irritable to light and sound. The pupils may at first be normal or contracted; ultimately they become dilated. In the more dangerous cases he quickly becomes delirious, with or without convulsions, or passes into a condition of insensibility. Even when he is deeply comatose he often still feels the pain in the head, and groans or cries out, or grasps the temples between his hands. Aphasia, hemiplegia, and other paralytic symptoms of this cephalic group are sometimes observed; but in the most severe cases of all their presence can hardly be determined.

The *muscular rigidity* of the neck already referred to is scarcely ever entirely absent, but is not commonly a marked symptom during the first day or two. It varies in degree from a slight stiffness, noticed only when an attempt is made to bend the head forwards up to a forcible retraction, bringing the occiput almost to a right angle with the spine. Dr Burdon Sanderson has suggested that it is due to a half-voluntary effort on the part of the patient for the relief of pain in the muscles; but it may be present when there is not pain at all, either in the neck or in the back. It would seem, however, that the muscles below the occipital bone do not feel as hard as might be expected; for Sanderson could not detect any tightness of them so long as the head was thrown back, and Ziemssen probably means little more when he says that the tetanic spasm is "limited to the deeper muscles, the trapezii almost invariably escaping." In about half the cases this symptom is accompanied by a contraction of the extensor muscles of the dorsal and the lumbar vertebræ. Sometimes the back is arched so as to be in a state of opisthotonos, but more often it is straightened into what Ziemssen calls *orthotonus*. If an attempt is made to raise the patient, he either slips down to the foot of the bed without bending his back at all, or allows his body to be lifted a very little way, and at the cost of so much pain that he is very soon put back into the recumbent posture. Almost always he lies on one side with his knees drawn up. He may then be nearly free from pain in the back, but sometimes its intensity is hardly at all affected by the position of the body; it is apt to be particularly severe in the sacrum. Pains in the limbs, and especially in the legs, are often complained of; some writers lay stress on the frequency of an acute pain in the knee. The joints may become hot, red, and painful, as is the case in other spinal affections. An extreme cutaneous hyperæsthesia is another common symptom; the patient, though he may be comatose, will perhaps scream out at the slightest touch, or even if his bed is shaken. Tetanic rigidity of the limbs is seldom present, and so also trismus is of infrequent occurrence.

The degree of *fever* in epidemic meningitis is exceedingly variable, and its course is very irregular, so that even those observers who lay most stress

on the typical fever-courses of many other specific diseases admit that nothing of the kind can be traced here. The temperature usually ranges from 100° to 103°, but it may fall and remain normal or nearly so for a day or two at a time; sometimes it rises to 105° or 107°, especially towards the last. The rate of the pulse may be natural or slightly increased; it is liable to frequent fluctuations; in bad cases it may be very rapid. The face is generally pale. The spleen is sometimes, but rarely, found enlarged. As a rule, the abdomen is retracted, but it may be greatly distended. Ziemssen observed several cases in which there was oppression at the epigastrium, constriction of the chest, or even paroxysms of dyspnœa. An abundant secretion of urine has been noticed by several German physicians, notwithstanding high fever; in exceptional cases a small quantity of albumen or of sugar has been present.

An important symptom in this, as compared with other forms of meningitis, is the occurrence of certain *cutaneous eruptions*. Chief among them is herpes of the face. This generally begins on the lips and spreads to the cheek, nose, ear, eyelids; it is often bilateral, and may cover the whole side of the face, as it does not in any other acute disease. It first appears between the third and the sixth day, but fresh outbreaks may take place as late as the sixth or the seventh week. It is sometimes seen on the trunk or on the limbs; but those parts are more often the seat of a roseola, erythema, urticaria, or purpura. There appears to be nothing specific in the characters of any of these eruptions; they are often mixed together in the same case. Ziemssen lays stress on the symmetry with which they are distributed on opposite sides of the median line—herpes on each wrist, urticaria on each leg, or petechiæ on each shoulder. Dr Collins, of Dublin, saw purpuric spots suppurate and scab over, so that they finally left pitted cicatrices. Sometimes large patches of hæmorrhage coalesce and give a uniform purple hue to a considerable part of the body.

The organs of *sight and hearing* are affected in many cases of cerebro-spinal fever. There is often intense conjunctivitis, attended with chemosis. Ulceration of the cornea, irido-choroiditis, or optic neuritis, may develop. Vision may be suddenly lost at an early period of the disease; and is often not regained if the patient recover.

The hearing was found by von Ziemssen to suffer in eight cases out of forty-two. Pain, tinnitus, impairment of hearing were generally experienced soon after the patient fell ill; they either passed off or ended in a partial or total deafness. Such symptoms sometimes depend upon suppuration of the tympanum, leading to perforation and discharge through the meatus. It has been suggested that in other instances they may be direct results of inflammation of the floor of the fourth ventricle, involving the *striæ acusticæ*, or that they may be due to suppuration around the seventh pair of nerves. In certain cases in which deafness had been present, Heller discovered after death a suppurative process in the labyrinth, besides an infiltration of the portio mollis with pus. It then became a question whether these morbid changes were caused by an extension of mischief from the pia mater, or whether they began simultaneously with the meningitis. Heller was disposed to adopt the former opinion. It is curious that in cases of this kind the portio dura constantly escapes, so that facial paralysis is not observed. Severe inflammation of the labyrinth usually leads to an absolute loss of hearing; and in most cases both ears are affected. The consequence is that the patient, if very young, never learns to speak. Even children two or three years old

who were able to talk before they fell ill with the meningitis, and whose articulation after their recovery was at first tolerably distinct, soon begin to lose the power of speech, and ultimately become unintelligible. How important a part epidemic meningitis sometimes takes in the production of deaf-mutism is shown by the fact that in 1874 every one of the inmates of an asylum at Bamberg owed the defect to this disease.

Varieties.—Cerebro-spinal fever has many degrees of severity, so that several distinct forms have been described. Some cases are called *foudroyant* or fulminant, the patient dying within a few hours from the commencement of his illness. Thus Dr Gordon recorded one instance in Ireland in which the disease ran a fatal course in less than five hours. There was a dark purplish eruption of spots of various sizes and shapes, especially upon the lower limbs. Ziemssen says that among forty-three cases he met with four in which the duration was from twelve to thirty hours. He relates a curious instance of a girl who was attacked one afternoon with headache and vomiting, but who got up in the middle of the following day feeling perfectly well, and went out of doors to fetch some beer; at about 2 o'clock she was again seized with violent headache and fell into convulsions, and at 6.30 she died. This form of the disease is seen chiefly at the beginning of an epidemic. According to Ziemssen, the presence of meningitis is discoverable only with the aid of a microscope, which reveals exuded leucocytes, principally along the blood-vessels. But in Dr Gordon's case greenish lymph had already been poured out both on the brain and at intervals along the cord.

On the other hand, there are cases which are termed *abortive*, in which the patient is only confined to bed for a day or two, or may even go on with his work as usual from the beginning to the end of his illness. Ziemssen has recorded in detail three examples of this form of the disease; in each of them headache, a painful stiffness of the neck, and vomiting (or at least nausea) were present; in one there was also rigidity of the upper dorsal vertebræ, and in another herpes and partial deafness were observed. In every instance recovery took place within four or five days. Abortive cases are said to be especially numerous when an epidemic is declining. Their proportionate frequency is very variable. According to Hirsch it sometimes happens that the greater part of the population of a district in which cerebro-spinal fever is prevalent are affected by this mild variety of the disease. Or it may be seen in the adults and the old people, while the severe form is raging among the children. To what extent the morbid changes in the membranes are developed in cases of this kind is as yet altogether unknown.

As a rule, however, the severity of epidemic meningitis is intermediate between these two extremes. If it terminates in recovery, it does not begin to subside before the end of a week or a fortnight.

There are certain other modifications of the disease to which brief reference must be made.

One is an *intermittent* form, in which there are regular paroxysms of fever, recurring after a quotidian or tertian type, with aggravation of all the other symptoms, the intervals being more or less completely apyretic. There are two ways in which cases of this kind have been explained; one supposition has been that they depend on the combined action of the marsh poison and of the specific poison of epidemic meningitis; the other, that the last-named disease is itself really of malarial origin.

But it is evident that neither of these opinions is correct, for the intermittent variety has been observed in districts where ague does not occur. Moreover, Ziemssen has shown that when measured by the thermometer the fever is far from exhibiting the regular course of that disease: the remissions or intermissions often last over several days, the temperature is irregular, and it is unaffected by quinine.

Ziemssen further remarks that the districts in which this disease has prevailed have often been dry, sandy, elevated plateaus; and Hirsch, that it differs from ague in being especially apt to occur in the winter and spring. Yet another point of distinction is its tendency to attack children rather than adults.

Another so-called variety is the *typhoid*. This arises in protracted cases, and is marked by muttering delirium, a dry, brown tongue, sordes on the lips, involuntary evacuations, and bedsores.

Several observers have found that during or just after an epidemic of cerebro-spinal fever, meningitis has presented itself with unusual frequency as a complication of other acute diseases. This is especially apt to be the case with acute lobar pneumonia; no less than fourteen instances of it are recorded as having occurred in Erlangen between 1866 and 1872. It has also been noticed with pleurisy, acute tonsillitis, and scarlatinal nephritis. Many of the patients recover perfectly well, the headache and stiffness of the neck passing off as the symptoms of the primary malady subside; it may then be said that the meningitis is of the "abortive" variety. But not a few such cases terminate fatally; and the usual morbid changes in the membranes are then found at the autopsy.

Relapses are not very uncommon, even in cases of moderate severity, after a week or two of illness; and even when the patient's recovery is uninterrupted, it is often very slow. The headache sometimes continues throughout his convalescence, and may persist for years afterwards, undergoing aggravation when he stoops or makes any mental or bodily effort.

Sequelæ.—These symptoms may probably be referred to cicatricial thickening of the pia mater, and this has been actually found present when there has been an opportunity of making an autopsy, at an interval after recovery from epidemic meningitis, in consequence of *chronic hydrocephalus* having developed itself as a sequela. Recent observations seem to show that this is not an infrequent occurrence. Ziemssen has recorded three instances in which death happened ten weeks, twenty-seven weeks, and thirty weeks respectively from the commencement of the patient's illness; and one in which it took place as late as seven years after. In all of them the membranes were thickened and opaque in different places; and twice cheesy masses were found upon the convexity as well as at the base of the brain. The quantity of fluid in the ventricles was often very great; in the case which proved fatal at the end of thirty weeks—that of a boy, two years old—the thickness of the hemisphere (white and grey matter together) was only about an inch. A sufficient explanation of the occurrence of hydrocephalus under such circumstances may perhaps be found in the persistence of the inflammation of the ependyma which exists during the acute stage of the disease. But, as Ziemssen remarks, the fact that between the meningitis itself and the commencement of the symptoms of the ventricular effusion there is often a clear interval, during which convalescence appears to be going on favourably, tends to support the opinion that the secondary

affection is in some way dependent on the cicatricial changes in the membranes. Niemeyer has suggested that the outflow of blood through the veins of Galen is interfered with by pressure. Dr Collins, of Dublin, in a case which he examined on the sixty-sixth day, found the cerebro-spinal opening between the cerebellum and the bulb occluded, and attributed to this the hydrocephalus, in accordance with the well-known views of Mr Hilton. But in a series of cases recorded by Dr Merkel, of Nuremberg, in vol. i of the 'Deutsches Archiv,' it was noticed that there was always also a large quantity of fluid beneath the arachnoid around the *cauda equina*. This, it is obvious, is altogether inexplicable on the mechanical theories just referred to. And on the whole it seems best to fall back upon the idea of a chronic ependymal inflammation, which indeed is directly supported by the histological investigations of Merkel, who found the ventricular lining and its vessels thickly set with nuclei.

The symptoms which indicate the supervention of hydrocephalus are said by Ziemssen to be chiefly severe headache, and pains in the back and limbs, occurring only in paroxysms, and attended with vomiting, loss of consciousness, convulsions, and the involuntary discharge of fæces and urine. During the intervals, which may last for weeks at a time, the patient may appear to be in good health, mentally and bodily; but very often he is dull and stupid, or he is affected with a general cutaneous hyperæsthesia, or with paralysis or contraction of one or more of the limbs. Progressive emaciation appears to be another marked symptom. Whether it is possible for recovery to take place from the hydrocephalus is as yet uncertain. It is to be noted that failure of memory and weakness of intelligence, when they immediately follow an attack of epidemic meningitis, do not point to the presence of ventricular effusion, and are not of evil omen, since they generally pass off in the course of a few months; and the same thing may be said of various paralytic affections which are now and then observed during convalescence from the disease.

Ætiology.—The causes of epidemic meningitis and its relations to other specific diseases are still very obscure. Those who are attacked by it are comparatively seldom over forty, and generally less than twenty, years of age; in some epidemics almost all the cases have been in children under fifteen. But two of Ziemssen's patients were old people, aged seventy and seventy-seven respectively. Males appear to be more often affected than females. Ziemssen says that it chiefly seizes upon strong, healthy subjects; but he and other observers are agreed that it is apt to be especially prevalent among the poor, who are ill-fed, and who live crowded together in dirty, damp, ill-ventilated dwellings. When it occurred in France at the beginning of the century it was often entirely limited to the soldiers in barracks, the civil population in the same towns escaping entirely. In Ireland, in 1846, it affected principally the inmates of the workhouses; in the United States it fell with especial severity upon the negroes.

Some of the facts just mentioned would seem to indicate that epidemic meningitis resembles typhus in its distribution, and may therefore be infectious. But of its being contagious in a narrow sense there is no evidence whatever. All observers are agreed that it does not pass from the sick to the healthy directly under ordinary circumstances. Hirsch, however, has collected a series of cases which seem to show that a man going from an infected to a healthy place may sometimes carry with him

the germs of the disease, so that not only he himself afterwards falls ill with it, but others are attacked in their turn. One suggestion is that a contagious principle is given off by the sick, but that it has to undergo some transformation or intermediate stage of its development, possibly in another animal, before it can infect a human being. It is stated, on the authority of Mr Ferguson, Veterinary Officer to the Privy Council in Ireland, that on each occasion when the disease has prevailed in that country there has been an epizootic of the same kind among pigs and dogs.

The transmission of a contagion, if there be one, is unusually rapid and mysterious. Dr Sanderson reported that in 1865 meningitis broke out on or about January 15th in two districts of the department of Dantzic, distant at least thirty miles from each other. So, again, Stillé insists on its having repeatedly prevailed in Europe and in America in the same years, and on the way in which it has made its appearance within the United States at places hundreds of miles apart. In this respect he compares it with influenza, and defines it as a pandemic disease.

Diagnosis.—This is seldom difficult. At the commencement of an outbreak, however, it would seem that enteric fever may sometimes be mistaken for it. Leyden says that among the German troops before Paris in 1870 a series of cases occurred in which marked rigidity of the neck, severe headache, and hyperæsthesia were present, while the abdomen was flat, the temperature was low, and the bowels were confined. At first it was doubtful whether the disease was not meningitis, but the autopsies showed that it was really typhoid fever, with but slight implication of the intestine. Epidemics of the two diseases may also prevail simultaneously. Leyden has seen this several times; he insists on the facial herpes as distinctive, since it is never observed in enteric fever.

When occurring as a complication of acute pneumonia, epidemic meningitis may be far from easy of diagnosis. Ziemssen remarks that rigidity of the neck is often entirely absent in such cases. In very young children, too, this symptom possesses very little significance even when it is present; and convulsions, coma, and other signs of cerebral disturbance are equally without value. Maurer maintains that a tense projecting fontanelle affords great help, since it proves that the intra-cranial pressure is excessive, and this is not likely to be the result of simple pneumonia.

Again, if an isolated case of meningitis should occur, it is often impossible to say whether it belongs to the epidemic, the simple, or to the tubercular form. It would seem that the spinal symptoms—the painful stiffness of the neck, the rigidity of the vertebræ, the hyperæsthesia, and pains in the limbs—are generally more marked in the epidemic disease. Tubercular meningitis may often be distinguised by its prodromata, by its gradual onset, by its slow and interrupted course. The presence of a roseolous or purpuric eruption would probably be a conclusive proof that the case was one of cerebro-spinal fever.

In giving a *prognosis* it is important to bear in mind the treacherous character of the disease. A case which at first appears to be of but little severity may afterwards develop dangerous symptoms and prove rapidly fatal; while, on the other hand, patients whose condition had seemed hopeless sometimes recover.

The *mortality* appears to vary in different epidemics from 30 to 70 per cent.; the mean mortality is estimated at 40 per cent.

Treatment of meningitis generally.—At an early stage one important object is to relieve the headache and to diminish the cerebral excitement. The patient should be placed in a cool, dark, well-ventilated room, and should be kept perfectly quiet. The hair should be cut short or shaved. Cold should be applied to the head, and for this purpose a large bladder containing small pieces of ice and a little water is more serviceable than anything else; evaporating lotions are far less effective, and require very frequent renewal.*

In epidemic meningitis Ziemssen and other German physicians keep ice-bags to the head, back, and neck for weeks together, and find that they relieve the patient's sufferings, and enable him to sleep.

Most physicians abstain from administering anodynes in cases of meningitis, as being likely to mask the symptoms; but at an early period of the disease this objection seems unfounded, and Dr Bristowe says that he has frequently given opium with manifest relief. Huguenin recommends the subcutaneous injection of morphia in small doses, and the use of enemata containing fifteen to forty-five grains of chloral. Ziemssen says that in epidemic meningitis remedies of this class are indispensable.

To check vomiting the patient may have little pieces of ice to suck; or bismuth, hydrocyanic acid, and similar remedies may be prescribed.

There is perhaps no reason to suppose that leeches, or venesection, or the most active purging could cut short a meningitis which is going on to the effusion of lymph and pus. But is it equally certain that such measures are useless in those cases which are less severe? In epidemic meningitis German authorities now recommend all those "antiphlogistic" measures which were in vogue in this country thirty years ago. They not only apply leeches behind the ears and cupping-glasses to the spine; in the most acute

* In 1878 I saw a case which appeared clearly to demonstrate the usefulness of the local application of ice. A man aged forty-three, a baker, was taken with a kind of fit on the evening of the 26th of June, and was seen the same night by Dr Churchward with a temperature of 104·6°, a pulse of 160, a very flushed, hot face, vomiting, and great pain in the head and neck, as well as in the back and in the limbs. He had been driving about all day in a hot sun; three days previously he had stood for some hours in water up to his knees in consequence of his cellars having been flooded by a heavy rainfall; for more than a month he had been unusually irritable in his temper. For a day or two he seemed to improve, but during the night of the 28th he became collapsed and almost pulseless, with a cold clammy sweat. After this he remained sleepless and was very delirious, with contracted pupils and constant twitching of the hands. On the 30th I saw him and found the optic discs normal; his symptoms were then of the most alarming character. We prescribed a mixture containing the iodide and the bromide of potassium, and a draught of chloral and morphia in the hope of inducing sleep. Next day (July 1st) he appeared to be rather worse than better; he had not slept for more than five minutes; he had been sick again; he was constantly talking and picking the bedclothes. Dr Churchward therefore ordered a towel to be wrung out of iced water, and to be kept applied all over his head and neck with lumps of ice between the folds. The effect seemed to be magical; in a few hours he became quiet and fell asleep; the sickness and the clammy perspirations ceased. He liked the cold to his head, and during the night he slept for six hours. On the following day (July 2nd) he was rational, and told Dr Churchward that he remembered nothing since the 29th June, except that another doctor had examined his eyes. The ice was continued until July 4th. His recovery was uninterrupted; on the 7th he got upon the sofa, and by the 11th he was able to be drawn out in a carriage. This patient died in the spring of 1880 of acute pneumonia. Dr Churchward obtained for me permission to examine his brain. There was no conspicuous change,—nothing, I think, that would have attracted my notice if I had not known of his former illness. But the arachnoid and pia mater at the base of the brain appeared to me to be thicker and crisper than natural, especially over the right Sylvian fissure; the olfactory lobes were more firmly bound down; and there was more connective tissue on the under surface of the pons. The velum interpositum also seemed to be increased in density, although the lateral ventricles were not dilated.—C. H. F.

cases, or when the patient is very restless, they employ venæsection; and they administer calomel, or rub in blue ointment, at the same time washing out the mouth with solution of chlorate of potass, to prevent the gums from being affected by the mercury.

In simple meningitis the older English physicians believed that they had seen successful results from energetic treatment.*

It is, no doubt, possible that the favourable issue of such cases was spontaneous, and would have occurred independently of all active treatment. But, on the other hand, it may be that under the negative practice of the present day they would have terminated fatally.

Of course it is essential that our treatment should do no harm. When there is any doubt of the diagnosis between enteric fever and tubercular meningitis, it would be very wrong to purge. Other cases in which uncertainty of diagnosis ought to influence our practice, are those of probable meningitis secondary to disease of the ear. This form of the disease is almost certainly hopeless, but we have already seen that pyæmia may simulate it very closely.

Again, in adult patients it is of the utmost importance that we should not overlook the possibility that syphilis may be the cause of symptoms resembling those of meningitis. We have seen that it may give rise to inflammation of the membranes of the brain, but it does not follow that syphilitic meningitis would be especially amenable to treatment. The point is rather that one may be called in to see a man who is insensible, and that the history of the case may seem to point to meningitis, but that the lesion may really be one of the more direct results of syphilis. It would then be cruel to ask of a wife, or of a mother, questions which might leave the most painful impressions, and which, if answered negatively, could never decide the matter. But the most careful search should be made for

* Some of Abercrombie's cases will perhaps still bear quotation. (Case 69), "A girl, aged eleven, had violent headache and vomiting, with great obstinacy of the bowels, and these symptoms were followed by dilated pupils and a degree of stupor bordering on perfect coma; pulse 130. She had been ill five or six days; purgatives, blistering, and mercury to salivation had been employed without benefit. One bleeding from the arm gave an immediate turn to this case; the headache was relieved; the pulse came down; the vomiting ceased; the bowels were freely acted upon by the medicines which they had previously resisted; and in a few days she was quite well." (Case 72), "A gentleman, aged twenty-one, was first affected with confusion of thought and very considerable loss of recollection. He then complained of headache, and after a day or two had double vision. At this time he was out of bed the greater part of the day, but was restless and confused, and at times incoherent. He was then confined to bed, and had constant headache, much incoherence and oppression, the double vision continuing. The pulse was at first frequent, but fell gradually and sank below the natural standard; and the symptoms went through a course exactly similar to that which has been described in many of the fatal cases. As the pulse fell in frequency he became more and more oppressed, until he sank into a state of stupor, from which he could scarcely be roused to answer a question of the most simple kind. The case went on in this manner for eight or ten days, during which time he was treated by repeated general and topical bleeding, cold applications, blistering, &c. The bowels were very obstinate, and large doses of the most active purgatives were given with little effect. The case was considered desperate, when he began to take croton oil in full doses, repeated every two or three hours. In a few hours he was purged very actively nine or ten times; the same evening he was relieved from every alarming symptom, and in a few days he was free from complaint." (Case 75), "A girl, aged seven, had severe headache, impatience of light, fever and slight delirium, followed by stupor, squinting, and great obstinacy of the bowels. The tongue was at first foul, but became clean after a day or two. . . . She was considered as being in a hopeless state of hydrocephalus. At the end of a week, strong purging being produced, she recovered rapidly, and in a few days was free from complaint."—'Diseases of Brain and Spinal Cord,' 3rd ed., 1834, pp. 155, 157, 158.

evidence of syphilis, such as the presence of nodes or gummata, and the recurrence of miscarriages or sterility on the part of the wife. If there is any reason to suppose that this cause may be in operation, full doses of the bichloride of mercury or of the iodide of potassium should be given. If this treatment is unsuccessful it can do no harm, and its success is sometimes very great. Whether it is advisable to prescribe iodide of potassium or mercurials (except in purgative doses), in cases which are believed to be idiopathic meningitis, is very doubtful.

As to the stage when coma sets in, Sir Thomas Watson says that in his experience the patient has sometimes recovered consciousness after a cap of blistering plaster has been put upon his head. He does not tell us whether the improvement was permanent. Huguenin speaks in high terms of the value of energetic cold affusion for the same purpose. But it seems possible that to excite a merely temporary return of consciousness might be injurious instead of beneficial. The application of mustard plasters to the calves of the legs must surely be altogether futile. Our endeavour should rather be to sustain life from hour to hour, in the hope that the tide may turn. Sir Thomas Waston remarks that "patients apparently moribund are occasionally saved by the judicious administration of stimulants and restoratives, of ammonia, Hoffmann's anodyne, beef-tea, wine, and (it may be) of well-timed opiates."

HYDROCEPHALUS.*—Among the diseases to which infants and young children are liable is distension of the cerebral ventricles with fluid.

Origin.—Hydrocephalus is sometimes *congenital.* At birth the fœtal head may be so large as to prevent its passage until it has burst or has been perforated by the instruments of the accoucheur. If the enlargement is less considerable, expulsion may at length take place, and the child may live for a shorter or a longer time. In slighter cases the head of the newly born infant is noticed to be softer and more pulpy than natural, but there is no obvious increase of size until a few weeks have passed. Among twenty-six cases collected by Dr Dickinson ('Lancet,' ii, 1870) there were four in which the disease was said to have been present from birth, sixteen in which it was discovered within the first six months, six in which it was not noticed until between the sixth and the twenty-sixth month. One must bear in mind that these figures express, not the relative frequency of the congenital and acquired forms of the disease (for the list probably includes no infants dying within the first week or two), but the number of cases of hydrocephalus as seen later on in childhood which are congenital. It is evidently impossible to determine in how many of them the hydrocephalus really began *in utero;* but probably in most the brain was healthy at the time of birth. We shall afterwards see that hydrocephalus sometimes arises at a more advanced period of life than in any of Dr Dickinson's cases.

Practical convenience prevents our describing separately the congenital and the acquired forms of hydrocephalus, as is done by Huguenin in Ziemssen's 'Handbuch,' nor does there appear to be any real difference in their pathology.

One supposed cause of "water on the brain" during early infancy is want of resistance in the parietes of the head, allowing the normal ventricular fluid to accumulate in excessive quantity, and thus to distend the

* *Synonyms.*—Chronic Hydrocephalus—Hydrocephalus internus—Water on the brain—Dropsy of the head.

ventricles. Huguenin says it is very common for rachitic children, if they are attacked with whooping-cough and bronchitis, to acquire a form of hydrocephalus due to this passive distension. Dr Dickinson and other observers, who have insisted on the frequency with which water on the brain occurs in cases of *rickets*, would include these cases as rachitic. The occasional association of hydrocephalus with congenital *syphilis* is supposed by Dr Dickinson to depend on a defective growth of the cranial bones, owing to the constitutional taint.

What little beside is known as to the ætiology of hydrocephalus tends, for the most part, to support the view that it is of an *inflammatory* origin.

A few striking instances of its occurrence in several children of the same father and mother have been recorded. Frank saw in one family six, in another seven cases. Gölis reported the case of a woman who aborted six times in succession with dead hydrocephalic fœtuses at the sixth month, and bore three living children, two of whom died of the same disease when eighteen months and three years old respectively. He adduced some facts to show that drunkenness on the part of either of the parents during procreation may dispose to hydrocephalus.

When it begins after birth, hydrocephalus appears sometimes to be directly traceable to an injury. West records the case of a little girl who, some months before her head began to enlarge, had fallen out of the arms of her nurse, and had subsequently been convulsed and comatose for some hours. In that instance the only structure that is said to have been thickened was the ependyma; but in many cases the membranes at the base of the brain are found opaque and adherent. There has been much difference of opinion as to whether hydrocephalus often arises out of acute meningitis. In the epidemic form of that affection such a termination is not infrequent (p. 658); but there is no evidence of its following tuberculous meningitis.*

Pathology.—It has been supposed that the physical and chemical properties of the hydrocephalic fluid enable one easily to determine whether the morbid process was of a passive or of an inflammatory origin. The normal cerebro-spinal fluid is well known to have a very low specific gravity, and to contain scarcely a trace of albumen. In some cases of hydrocephalus the fluid has possessed similar properties, and, according to C. Schmidt, the proportion in it of potass salts to soda salts, and that of phosphates to chlorides, have differed altogether from those which are met with in ordinary serum, and even in fluid derived from the membranes on the surface of the brain—a fact which is cited by Vogel as proving that the hydrocephalic fluid is a specific secretion of the choroid plexuses. But there are other cases in which the fluid has been of higher specific gravity, and has contained from 3 to 11·5 parts of albumen in 1000; and this is supposed to be a proof of the inflammatory nature of the exudation. The presence of leucocytes or of minute flakes of lymph is probably safer evidence. The author observed no less than four instances of the fluid being almost free from

* Huguenin, however, speaks most positively of having seen hydrocephalus begin with acute symptoms exactly like those of (non-tubercular) infantile lepto-meningitis, but which instead of terminating fatally, have subsided and passed into those of a chronic cerebral affection, attended with great enlargement of the head. He says that in such instances he has found the pia mater at the base of the brain thickened and opaque, and the choroid plexuses also showing traces of a former inflammatory change. In a case of this kind related in full detail by Rilliet and Barthez, in which the early active symptoms lasted six days, it is expressly stated that the ventricular fluid contained only a trace of albumen, that the ependyma was normal, and that there were no adhesions of the pia mater at the base.

albumen in cases which were of inflammatory origin. The patients were all adults, and there was no reason to believe that they had had hydrocephalus for more than a few months. Their cerebral symptoms were of recent development, and in one instance were distinctly traceable to an injury.

Several pathologists have shown that there is sometimes closure by adhesions, either of the foramen* at the lower angle of the fourth ventricle, or of the aqueduct of Sylvius; and Hilton propounded the doctrine that the obliteration of these channels is often the cause of hydrocephalus, by preventing the outflow of the normal intra-ventricular fluid into the sub-arachnoid space of the cord, which ought to occur whenever increase in the physiological activity of the brain leads to an increase of its supply of blood. But it is difficult to see why the fluid should continue to be poured out under the increased pressure which must necessarily result, and which certainly is present in most cases of hydrocephalus. Moreover, since the adhesions themselves are the results of a more or less widely diffused meningitis, such as is often attended with an inflammatory change in the ependyma, it would seem more reasonable to regard this as the cause of the effusion than to adopt Hilton's theory. It is well known that in one and the same case the various serous membranes may pour out fluids of very different specific gravity; and it is not improbable that the ventricles of the brain may continue to secrete a fluid containing scarcely any albumen, even when the process is inflammatory. But the question can only be settled by careful observations as to the state of the openings into the fourth ventricle in a series of cases of hydrocephalus in which the physical and chemical properties of the fluid are also accurately determined.

The quantity of water on the brain in cases of long standing is sometimes very great; six, eight, twenty, even twenty-seven pints have been measured after death in different cases. The hemispheres are transformed into a thin shell, perhaps not more than a line or two in thickness, so that it is difficult to understand how they retained any of their functions. The distinction between the white and the grey matter is lost; and the sulci, if visible at all, appear only as shallow grooves beneath the pia mater. The nerve-cells are said to be more or less completely atrophied and destroyed; but accurate histological details seem to be still needed. The corpora striata and the thalami are flattened and broad, as are the crura cerebri, the pons, and other structures at the base. The weight of the brain is in most cases much reduced. Some of the more delicate structures, such as the septum lucidum and the soft commissure, are defective or absent, probably in consequence of the stretching to which they have been subjected. The foramen of Monro and the aqueduct between the third and fourth ventricles are generally widely dilated. The ependyma is generally thick, tougher than natural, and of an opaque white or grey colour. It often contains a large number of amyloid bodies. Its free surface is covered with granulations, or with a number of translucent beads which give it an appearance aptly compared by Dr Moxon to the leaf of an ice-plant.

Under the name of *Hydrocephalus externus* a separate variety of the disease has been described, in which the seat of the effusion is said to be the subdural (arachnoid) space. No doubt this may be the case where there is an extreme degree of malformation of the brain, as in some microcephalic or anencephalous fœtuses, but Dr Wilks has always disbelieved in

* See Cruveilhier, tom. iii, p. 385; and Hilton, on 'Rest and Pain,' 3rd ed., p. 23, and figs. 1, 2, 8, and 9, with Mr Jacobson's note, p. 39.

the occurrence of external hydrocephalus under other conditions. The classical example is that of James Cardinal, recorded by Dr Bright, who died in 1824, at the age of twenty-nine, in Guy's Hospital. The total quantity of fluid in this case was seven or eight pints, and all of it, with the exception of one pint, lay beneath the dura mater at the time of the autopsy. There was, however, a hole in the corpus callosum, and Bright himself supposed that the ventricles were the original seat of the effusion. Dr Wilks believes that the rupture through the corpus callosum did not take place until just before death; and it is evident that the case cannot be fairly cited as an instance of a special form of hydrocephalus (see Catalogue of Museum, No. 1000).

Congenital hydrocephalus is often associated with malformation of other parts as well as of the brain itself. It is seen in combination with spina bifida, and in one of these cases at Guy's Hospital the central canal of the cord was greatly dilated.

A certain degree of secondary dilatation of the ventricles is common in cases of cerebral tumour. This is seldom a matter of clinical interest; but sometimes, when the cranium becomes enlarged, the disease is mistaken for primary hydrocephalus, until a new growth is discovered at the autopsy.

Anatomy.—Enlargement of the head is usually the first, as well as the principal symptom of the hydrocephalus of early childhood. Among forty-five cases collected by West there were twelve in which the frequent repetition of fits first drew attention to the disease, four in which it began with some other indication of cerebral disturbance, and six in which it arose out of an acute attack: in the remaining twenty-three cases no definite cerebral symptom preceded the discovery that the head was increasing in size.

The effect of the disease upon the cranial bones is to separate them more and more widely except at the base. Trousseau compared the change to the falling back of the petals of an opening flower. The frontal bone rises vertically above the eyebrows, or even overhangs them; the temporal and parietal bones arch outwards, so as to hide the ears when the scalp is viewed from above; the occipital bone extends backwards almost horizontally. Thus the head may acquire an enormous circumference. Dr Dickinson had under his care a child nine months old, in whom it measured thirty-one inches, and instances in which it ultimately reached forty and even fifty-two inches are cited by Trousseau. A strange contrast is afforded by the shape of the face, which appears unnaturally small, with angular features and a sharp chin. The base of the skull is generally narrow, with shallow fossæ. The presence of the fluid in the anterior cornua of the ventricles affects the orbital plates, so that they become convex downwards instead of upwards, and thus arises a very important character of the disease in an abnormal position of each eyeball; a large part of the iris, and even of the pupil, is hidden by the lower lid, while the sclerotic above the cornea is exposed to view.

The vertex of the head forms an open area, which corresponds with the natural fontanelles, expanded so as to meet together between the parietal bones and dividing the two halves of the frontal bone by a cleft that reaches nearly to the root of the nose. There is always, however, a work of ossification going on which tends to cover the brain in, provided that the process of expansion is not the more active of the two. In examining the crania of hydrocephalic children, whose death has occurred while the

disease was in progress, the author has found that the original outlines of the bones were still plainly visible, but that they were surrounded by broad zones of new osseous material, marked by radiating lines which showed the direction of their growth. The closure of the skull is often hastened by the formation of *ossa triquetra*, which may be felt loose in the membrane. The date at which it is completed varies widely in different individuals. In Dr Bright's patient, Cardinal, the anterior fontanelle is said to have been finally ossified at about the twenty-seventh year. Sometimes irregularities seem to occur in the union of the several bones. At least this has been assumed to be the cause of a want of symmetry in the cranium which has sometimes been noticed. As a rule the shape of a hydrocephalic skull approaches that of a sphere. It often, however, appears somewhat quadrilateral from the projection of the frontal and parietal eminences. The bones have no diploë; they are generally very thin, and are sometimes translucent; but where life had been prolonged past middle age they have been found greatly thickened. The museum of Guy's Hospital contains a specimen of extensive ossification of the dura mater, which was taken from a case of this kind.

The separation of the bones of the head by an accumulation of fluid within the cranial cavity is not altogether confined to infants. There is a classical case, recorded by Matthew Baillie, of a boy, aged seven, whose skull had appeared to be firmly united, but in whom at the time of death there was an interval of three quarters of an inch at the sagittal, and one of half an inch at the coronal suture. Dr Dickinson says that the same thing has been known to occur in adults; but even in children it is exceedingly infrequent when the bones have once become interlocked.

Physical signs.—In well-marked cases of hydrocephalus it is easy to transmit a wave of fluctuation from one hand to the other across the distended scalp. The skin and the subcutaneous tissues are exceedingly thin, and the ramifications of large veins are often plainly visible through the scanty hair. The head may appear obviously translucent when a candle is held on the opposite side of it. In Cardinal's case this was observed, if the sun was shining behind him, until he was fourteen years old.

Some German observers state they have elicited a *bruit de pôt fêlé* on percussing a hydrocephalic head, especially when the mouth was opened; it is supposed to have been due to resonance of the air in the vault of the pharynx. Auscultation has also been brought to bear upon the diagnosis of the disease. It is well known that on listening over the fontanelle of a healthy child one hears a systolic murmur; this has been supposed to arise in the veins that open into the longitudinal sinus, as a consequence of their being compressed at the moment when the cerebral arteries become distended with blood. Now Rilliet and Barthez maintained that in hydrocephalus this murmur is not to be discovered; but more recent observers have shown that it may often be plainly heard, although they admit that it is absent in acute meningitis, or where effusion is going on very rapidly. The contradictory statements which have been made may be in part due to the fact that even under normal conditions this cranial murmur is only audible between the eighteenth week and the fourth year.

Symptoms.—One consequence of hydrocephalus is a difficulty in keeping the head supported. An infant is often unable to raise it from the pillow, and, if placed in a sitting posture, lets it roll backwards and forwards, as if it had no power in its cervical muscles. An older child perhaps sits with

the head resting on the table, or walks with it carried between his hands, "just as a milkmaid steadies her pail."

In those rare instances in which a skull already fully developed expands under the influence of the disease (as in Baillie's patient already referred to), headache, stupor, and paralysis of all the limbs may be present for several months before any enlargement is noticed. Such cases are transitional between the hydrocephalus of early childhood and that of adult life. But in young children, in whom the cranial cavity readily yields, it is often surprising how few symptoms of cerebral disturbance can be made out, even when the quantity of fluid is already large. Headache is often present; even very young children show that they are in pain by restlessness and a sad whining cry. Vomiting is of frequent occurrence, and, like the headache, it is apt to be excited by movements of the head, especially when the child assumes the erect posture.

The *sight* sometimes remains good throughout the whole course of the disease; but in many instances there is blindness almost from the commencement, due to changes in the optic discs, which are commonly white and atrophied. It is probable that this sometimes occurs as the direct result of the pressure of the ventricular effusion upon the optic tracts; but in many instances it is secondary to "choking" or to neuritis. Huguenin examined three infants with congenital hydrocephalus between the twentieth and the thirty-fifth day after birth, and in each case found the discs reddened and swollen.

The *hearing* is very seldom impaired; as Dr Dickinson remarks, a young child who is perfectly blind may at once recognise its mother by her voice. The smell is said to be sometimes absent, and the olfactory lobes atrophied. Probably in such cases there would be other malformations of the nervous centres as well. The *taste* seems often to be perverted; for the appetite is voracious and indiscriminate.

Impairment of the muscular power of the limbs may be present in all degrees from a slight failure of co-ordination in standing or walking, up to a total paralysis. There is sometimes more or less complete hemiplegia or paraplegia, but such symptoms probably depend upon some additional local lesion of the brain or cord. Spasmodic affections of various kinds occur; nystagmus especially, but also partial clonic or tonic spasms of the limbs, and even general epileptiform convulsions, the latter being very apt to be brought on by any accidental circumstance which shakes the head or gives it a mechanical shock. The legs and arms are often stunted in their growth, and their muscles very small. Huguenin mentions that in one case, in which the lower limbs were for a time contracted but afterwards became relaxed, the muscles were found to have lost their contractility to faradic currents; indicating that there was some secondary or concomitant affection of the grey matter of the cord.

In some cases of congenital hydrocephalus there is no advance of intelligence from the time of birth onwards; and they generally terminate fatally at an early age. In other instances the brain develops to some extent, but very slowly, taking perhaps ten times as long as usual. During childhood such patients would generally be classed as imbeciles.

Cardinal, however, went to school at the age of six, and he soon learnt to read well and to write a little; but he was obliged to give up the latter accomplishment, as stooping caused a pain in the head. When he was twenty-nine years old his mental faculties are said to have been "very fair.

His memory was tolerable, but it did not retain dates and periods of time; and it was stated of him that he had never been known to dream. There was something childish and irritable in his manner, and he was easily provoked. He was stated not to have sexual desire, but he was fond of society and affectionate to his mother. His voice was not manly, but feeble and somewhat hoarse." He died about three months later, having become exceedingly feeble, with a protracted cold, febrile symptoms, diarrhœa, and loss of appetite. Probably, if the lungs had been examined, it would have been found that phthisis was the cause of death.

In the Fulbourn Asylum the late Dr Bacon once showed the author a woman, aged fifty-three, whose head measured twenty-seven inches in circumference; yet she could sing and talk well, and had tolerably good memory and intelligence.

In some rare cases, in which hydrocephalus is thus arrested, the intellectual faculties are said to reach a normal or more than normal standard. The name of the author of 'Vanity Fair' has often been cited as an illustrious example of the fact. But it is doubtful whether the difficulty of distinguishing a rachitic enlargement of the head from "water on the brain" has been sufficiently taken into account in regard to such cases.

For, strange as it must appear, it is a fact that errors have not infrequently been committed, even by skilled observers, as to the presence of fluid within the cranial cavity; and not only has hypertrophy of the brain been mistaken for it, but it has sometimes turned out that the disease has been nothing more than rickets. However, one can for the future avoid this particular blunder by measuring the circumference of the skull, and comparing it with what it should be, according to the age of the child, in a table of standard measurements, such as one which is given by Huguenin. And that writer says that even where the yielding of the softened bones leads to an accumulation of ventricular fluid in a rachitic infant, the ophthalmoscope enables the true character of the affection to be easily recognised, since the optic discs retain their normal appearance. But it is very doubtful whether such tests are applicable to the cases in which there is really most danger of diagnosing hydrocephalus wrongly. These are probably examples of the disease which will be described as hypertrophy of the brain (p. 691) in which the skull is much enlarged.*

Course.—The course and termination of hydrocephalus vary widely in different cases. Sometimes the disease undergoes a rapid advance, and destroys life in a few months by coma or by a succession of epileptiform seizures. Very often the child dies through some intercurrent malady, such as measles or whooping-cough; or, if he is rachitic, he is cut off by laryngismus stridulus or by some other complication. In certain very rare cases the fluid makes its way through the skull, and may even be discharged externally. Rokitansky once saw it poured out through the open sutures and diffused beneath the tissues outside the cranium. Several writers have recorded instances in which it has escaped through the nose, or even through the upper eyelid; and some of them have ended in the recovery of the patient. When the discharge takes place into the nasal fossæ it is supposed

* I suppose that it was a case of this kind which many years ago occurred to me at the Evelina Hospital, but of which I have unfortunately preserved no notes; during the child's life the presence of hydrocephalus was never doubted by me, nor by anyone else who saw it, although the necessity of caution in the diagnosis of that disease had already before that time been impressed upon my mind; but when the skull was opened it was found to contain nothing but a large solid brain.—C. H. F.

that the ethmoid bone must have been loosened from its attachments by the pressure to which it is subjected.

In 1884–85 the writer had a child under his care in Guy's Hospital with extreme hydrocephalus, whose case is worthy of note from its having been under continuous observation from the beginning of the disease till its end. The patient was a remarkably fine boy, six years old, and free from family proclivity to diseases of the brain. He first, while living in the country, began to lose power over his bladder, then he had occasional fits, vomiting, headache and staggering, with slight loss of power in the limbs, and then dimness of sight. We found optic neuritis. It was at first thought that there was a tumour of the superior vermiform process pressing on the veins of Galen and causing secondary hydrocephalus; but the subsequent course of the disease did not confirm this supposition. The child went through a slight attack of diphtheria. The head gradually enlarged, the gait became feeble, complete blindness with double optic atrophy followed, and at last he lay passive and almost motionless in bed with incontinence of fæces and urine, but almost always free from pain and with no convulsions or paralysis. During the last few weeks there was tonic contraction of the arms with ankle-clonus, and for the first time rapid loss of flesh. He died at the age of eight, having lived nearly two years in the hospital (Dec. 18th, 1885). *Post mortem* all the organs were healthy, except the brain, which was distended by serous effusion in both ventricles. The central canal of the cord was wider than usual in the cervical region, and there was early sclerosis of one lateral column.

Prognosis.—If the quantity of fluid is not large, and if the tendency for it to go on accumulating has never been very active, it often happens that the morbid action undergoes arrest after a time, and that as the child grows older the increased size of the head ceases to be conspicuous. Some years ago, in examining the body of a man, aged forty-three, who had been killed by an accident, the author found well-marked hydrocephalus, probably a residue of an attack of the disease in childhood; no information as to the man's mental capacity or attainments could be obtained. Persons have been known to live under such circumstances to advanced age.

It is, however, believed that cases of this kind have a marked tendency to relapse, and that excitement or overwork is apt to light up morbid changes afresh. It is supposed that there is special risk of this occurrence at the period when the ossification of the skull is finally completed.

Treatment.—The treatment of hydrocephalus is unsatisfactory. As might be expected, the drugs which are chiefly prescribed are those which increase the secretions of the kidneys, and thus promote the absorption of the fluid products of inflammation. Small quantities of grey powder or of calomel, pills containing mercury and squill in doses adapted to the age of the patient, the liquor hydrargyri perchloridi, and iodide of potassium are most frequently prescribed. It is doubtful whether benefit is obtained by such remedies, notwithstanding the two remarkable cases of Dr Gower's cited by Sir Thomas Watson.*

The frequent presence of rickets in hydrocephalic children would suggest

* In Lord Herbert's Life (c. 1625) he relates a very similar case. "My cosen, Athelstan Owen, having an hydrocephale in that extremity that his eyes began to start out of his head, and his tongue to come out of his mouth, . . . I prescribed for him the decoction of two diuretic roots, which after he had drank four or five days, he urined in that abundance that his head by degrees returned to its ancient figure, and all other signs of health appeared."

the administration of cod-liver oil and of the preparations of iron; with which, however, one may combine digitalis, or the acetate of potass, or the perchloride of mercury, if it should be deemed advisable.

The mode of treatment which has the largest amount of testimony in its favour consists in the application of pressure to the head. At one time it was usual to cover the whole of the scalp with strips of adhesive plaster. But of late it has been found sufficient to surround the head with a fillet of elastic webbing, two or three inches wide, and carefully adjusted, so as not to cause redness, or to impress the pattern of the material upon the skin. Care must also be taken to shift it from time to time, so that it may not irritate the frontal eminences. The necessity for such precautions is shown by the fact that sloughing of the integuments, leading to the death of the patient, has been known to occur when they have been neglected. Dr Dickinson speaks in high terms of this procedure, and says that it may be expected to succeed in arresting the disease in the majority of cases, provided that the child is young and that the enlargement of the head is of recent development. One instance which he relates in detail is that of a boy, aged thirteen months, whose skull had been growing out of proportion to the rest of the body for nine months, and measured twenty-two inches round. The eyes were depressed. There were occasional convulsive attacks. An elastic bandage was put on, and it was worn for three years, being renewed as often as was necessary. Diuretics and cod-liver oil were given during the same period. Within four months the circumference of the head became reduced to $20\frac{5}{8}$ inches. At the end of the treatment the bones were fully ossified; and although the head, which was then completely covered with hair, measured $21\frac{1}{2}$ or $21\frac{3}{4}$ inches, its disproportionate size was much less conspicuous. The position of the eyes was natural. There had been no convulsions for eighteen months. The child, at this time more than four years old, was sensible, and could make use of simple words for talking; but his memory was deficient.

Paracentesis of the head with a small trocar, at the outer angle of the great fontanelle, has been recommended by some physicians, and it has been performed on several occasions at Guy's Hospital. Perhaps the best thing that can be said in its favour is still the fact that in a case recorded many years ago by Mr Greatwood, a hydrocephalic child, having accidentally fallen upon a nail which penetrated its skull, recovered after three pints of fluid had slowly escaped through the wound. Cases are also on record of recovery after evacuation of the fluid through the nose. Scarcely less successful results have been reported after paracentesis; but the cases in question do not stand criticism.* Only a small quantity of fluid (not more than two or three ounces) should be withdrawn at a time, on account of the danger of setting up convulsions. If the result appears to be good, one may have recourse to the same procedure again and again, a bandage being applied in the intervals. But such repeated operations are very likely to be followed by acute meningitis, or to set up suppuration in the ventricles. It is doubtful whether this mode of treatment should be adopted, except in the hope of warding off death for the time, when it is threatened by epileptiform seizures or by coma. The injection of iodine into the distended ventricles has occasionally been practised, and has not

* See, for example, Dr West's remarks in 1842 on fifty-six cases of hydrocephalus treated by tapping the skull ('Lectures on Diseases of Children,' p. 130); and those of Dr Wilks ('Diseases of the Nervous System,' p. 175).

been followed by death; but there is no ground for supposing that it does good. After having several times practised paracentesis, Dr Eustace Smith has seen no decided benefit result, and sometimes decided evil, and Dr Goodhart speaks but little more favourably of the operation.

HYDROCEPHALUS OF ADULT LIFE; CHRONIC MENINGO-EPENDYMITIS.—Many writers state that adult patients are sometimes affected with a chronic disease of the brain, in which the most conspicuous anatomical change is distension of the ventricles with fluid. Dean Swift is said to have died of this malady, after an illness of three years' duration, in 1745; but one cannot speak confidently of the accuracy of an observation made so long ago, when scarcely anything was known of pathology. Sir Thomas Watson records the case of a young man, who, after one or two sudden attacks of unconsciousness, became dull, stupid, and insensible, and at length died; the only alteration that could be detected in the brain was the presence of a large quantity of serous fluid in the ventricles.

Pathologically there is a close correspondence between cases of this kind and those of hydrocephalus occurring in childhood. Similar changes are found in the ependyma of the ventricles; it is tough and thick, and may be granular and feel rough to the touch, or may have an areolated appearance, like that of the capsule of the liver in some cases of perihepatitis. The floor of the third ventricle often forms a protrusion like a bladder of fluid. The membranes at the base are found greatly thickened, opaque, and matted together; even more so in the affection of adults than in that of children. There is, of course, a great difference in the quantity of the fluid, which seems not to have exceeded fourteen ounces in any of the cases observed at Guy's Hospital within the last few years. Whenever its characters have been recorded, it was clear, and contained only very little albumen. The cranial bones are generally thin, and there is deficiency of the diploë; the interior of the skull is marked by sharp ridges, with sulci between them, which are obviously caused by the outward pressure of the brain. There is a marked flattening of the hemispheres.

Clinically, the relation between the hydrocephalus of adult life and that of childhood is one of contrast rather than of resemblance. The enlargement of the head, which renders the diagnosis of the disease so easy, is wanting; and in the symptoms which are present there is scarcely anything to distinguish it from other chronic affections of the brain.*

* The following are the more striking among fifteen cases recorded at Guy's Hospital. In all of them the ventricles were dilated with effusion: additional facts are added in brackets.

1. A man, aged twenty-three, a patient of Dr Wilks, said that he had been well until a year before, when he noticed a numbness in his feet and legs, which gradually extended up to his face. He had kept his bed for three months. A fortnight back he once found himself unable to micturate, so that a catheter had to be used. Within the last weeks he had had two fits, in which he was insensible. On admission there was a slight convergent squint; the pupils were dilated; the optic discs were ill-defined and red, with some plugging of the veins and retinal hæmorrhages. He had numbness of the feet and legs, and of the face about the mouth. He did not chew his food properly; portions of it would fall out of his mouth while he was eating. His mind seemed not to be clear; and his statements varied. He passed his urine into the bed. After a few days he died suddenly.

2. A man, aged thirty-two, under the care of Dr Pavy, had been obliged to give up work eighteen months before his admission into the hospital, on account of a pain in the head. Nine months ago he lost his speech, had right hemiplegia, and was insensible for three weeks. From that time his memory was imperfect. Eight days before his death he again became affected with partial hemiplegia and inability to speak. He passed his urine and fæces under him. During the last few hours of his life he had a series of fits, which began in the left side of the face, and in which the eyes were turned to the right.

It is clear, from the cases recorded below, that in the adult diagnosis between hydrocephalus and other chronic cerebral diseases is exceedingly difficult, if not impossible. Bilateral symptoms might suggest the nature of the disease, but hemiplegia is sometimes present, and seems to be indistinguishable from that which a tumour might cause.

Huguenin has attempted to give a systematic account of the hydrocephalus of adults; but his description of the symptoms in 'Ziemssen's Handbuch' by no means corresponds with our experience. He speaks of the affection as bearing the closest resemblance to general paralysis of the insane, and he gives full reports of two cases in which such a resemblance undoubtedly existed, although there was no *délire des grandeurs*. Neither of Huguenin's patients died in a general hospital; one was an inmate of the lunatic asylum at Zürich, the other was nursed at home. His cases

3. A man, aged fifty-seven, a cooper, was taken in with partial right hemiplegia, which had come on suddenly four days previously, while he was in the act of striking a piece of iron; he managed, however, to get home afterwards, the distance being half a mile. He did not seem very ill on admission, and looked a strong, healthy man; but he died rather suddenly, nine days after the attack. [In addition to immense distension of the ventricles, with roughening of the ependyma, there was in this case softening of the superficial parts of the corpora striata, and granule-masses were discovered with the microscope.]

4. A man, aged fifty-five, was admitted for chronic dilatation of the stomach, in order that the treatment with the stomach-pump might be carried out. But he became light-headed, and two days later he was convulsed and fell into a semi-comatose condition, in which he lay groaning and muttering until at the end of a few hours he died. He had complained of severe pains in the head three months before.

5. A boy, aged fifteen, who had two sisters in an asylum, was taken in with very obscure symptoms. He was anæmic; he vomited occasionally; there was slight fever; some of the superficial glands were swollen; he complained of pains in the head and in the back of the neck. After a time his mind began to wander; he lay on his side, with his legs drawn up; he answered questions slowly and unwillingly; his eyes were half closed and pupils dilated; the temperature was now below normal, sometimes not above 97°. He died very gradually.

6. A man, aged twenty-two, was admitted under Dr Habershon in 1871 for severe cerebral symptoms. He had once fallen from a scaffold, striking the left side of his head; and was insensible for a fortnight, with bleeding from the mouth, the nose, and the left ear. At the end of three months he resumed his work, but was noticed to be strange in manner. Seven months before his death he was attacked with violent headache and shivering. He gradually became unable to stand, and passed his urine and fæces under him. While in the hospital, he lay all day in a drowsy condition. He would answer questions, but soon began to ramble in his talk. He was occasionally sick, his pupils were dilated, and his head was drawn back. Two months before his death he had a fit; and a month later a second one. After this he lay perfectly still, saying nothing, and eating no solid food; towards the last he became extremely emaciated. [Besides well-marked indications of chronic meningitis, and a greatly dilated state of the ventricles, the anterior and middle lobes of the brain were adherent to the dura mater at the base, especially on the left side. There was a little ochrey-yellow discoloration, extending into the brain-substance, no doubt the result of effusion of blood at the time of the injury. The foramen of Magendie at the apex of the fourth ventricle appeared to be closed, so that the case might be cited in support of Hilton's theory of hydrocephalus (p. 665). The ventricular fluid contained scarcely any albumen.]

7. A man, aged thirty, a patient of Dr Wilks, died in the hospital in 1876, from disease of the aortic valves, and bronchitis. Towards the last he seems to have had no marked cerebral symptoms, but when admitted he was comatose, passing urine and fæces under him, and remained so for several days before he gradually recovered consciousness. His coma began with a succession of fits, and, while in the ward, he had one or two attacks affecting the left side.. He seemed intelligent, and answered questions readily. Eight years before, when he was a healthy young man, he had fallen from a ladder, and cut his head. He was brought home insensible, was delirious for two days, and was laid up for eleven weeks. Ever after he was unable to do any hard work. His memory failed him, he had headache, and feeling on the left side of the body gradually became defective. His first fit occurred five years before his admission. [Besides distension of the ventricles and the aqueduct, which held fourteen ounces of fluid, there was a repaired fracture of the base of the skull, and the brain on its under surface was discoloured.]

only afford additional proof of the variety of aspects that the disease may assume, and of the difficulty of its diagnosis.

In the last two of our cases hydrocephalus was attributable to a severe fall on the head. In one of Huguenin's patients a similar origin was no less directly traced, although the accident was a comparatively slight railway collision. It is an interesting and important question whether the occurrence of serious cerebral symptoms under such circumstances may be taken to indicate that chronic meningo-ependymitis with effusion into the ventricles is developing itself. There are, indeed, other possibilities to be taken into account. A tumour has sometimes been found where during life the symptoms were supposed to be of traumatic origin; and it may be that new growths are, in fact, sometimes set up by injuries. It has been commonly believed that an abscess is not unlikely to be met with in such cases, but this seems to be very doubtful. When cerebral disturbance has lasted for a long time, the only lesion discoverable may be an ochrey-yellow discoloration from bruising of the surface of the brain; or there may be none whatever. The author once examined the body of a man who died of some other disease, but who was said never to have recovered from the effects of an injury to the head, so that he was unable to take stimulants even in moderation; and in that instance the brain, the membranes, and the bones all appeared to be thoroughly healthy.

Huguenin refers to cases in which persons who had experienced blows or falls on the head, after suffering for several months, or even for years, have at length recovered; and he believes that they depend on chronic meningitis. He remarks that the chief symptoms are headache, giddiness, and other subjective sensations of a distressing character, which often cause the patient to withdraw himself from society. The pupils are sometimes unequal or sluggish. The author once had a case of this kind under observation. A bank porter, seven years before, had received a blow on the head from the heavy door of an iron safe; ever since he had been liable to pain in the occiput, vertigo, and a peculiar light feeling in the head. Sometimes he was free from these symptoms for weeks, but the least thing affected his head, so that he could take scarcely any stimulant. Reading often made him feel giddy; and he had been obliged to go out of church on account of indescribable discomfort. Once he complained of numbness in the left side of his head, and again of feeling as if his collar were too tight. The optic discs were normal.

The perchloride of mercury was more useful than any other medicine to this patient; on one occasion it entirely kept off his symptoms for about a year. He also took bromide of potassium and the ammoniated tincture of valerian; and a blister was once applied to the back of the neck.

In more severe cases of hydrocephalus (if that was the nature of these cases) similar measures appear to be the best. Huguenin advocates the continued application to the head of a bladder of ice or a stream of cold water; he also recommends periodical leeching, saline purgatives, and small doses of chloral for the relief of pain. The bromides he has found useful, but not the iodides nor mercurial preparations.

Plastic thrombosis of the sinuses of the dura mater.—This rare primary affection consists in plugging of one or more of the sinuses with a firm clot, which becomes closely adherent, sometimes laminated, and tends to undergo

organisation into permanent tissue. To von Dusch and Gerhardt we are indebted for the best account of it.

In the first edition of this work the author could only refer to a single case from the records at Guy's Hospital. Dr Pitt, in his 'Gulstonian Lectures' for 1890, quotes eight additional cases from the same source. Three were in infants, two in patients between 20 and 30 years of age, and three between 40 and 46; two of the adult patients were men, and three women.

The most usual seat of the thrombus is the longitudinal sinus; sometimes it extends into the tributary veins, so that the hemispheres appear to be covered with coiling worm-like bodies; sometimes it is prolonged into one of the lateral sinuses. In some instances hæmorrhage in the pia seems to have occurred as a consequence of this affection, in others the substance of the brain has been found ecchymosed or softened; but it appears doubtful whether those cases have been correctly interpreted.

There are certain conditions under which this form of thrombosis is especially apt to occur, and which, therefore, may suggest a suspicion of its presence. It has been observed in ill-nourished infants, six months or a year old, who have suffered severely from diarrhœa for some weeks before their death. Such cases generally resemble those of the "spurious hydrocephalus" described at p. 644, but with the addition of some more definite cerebral symptoms, such as nystagmus, squinting, ptosis, facial paralysis, and especially rigidity of the neck, back, or limbs. The fontanelle is generally sunken, but in one of Gerhardt's cases it became tense towards the last.

In adults, adhesive thrombosis of the sinuses seems sometimes to occur spontaneously; sometimes it is consecutive to enteric fever, or to parturition, especially when much blood has been lost. Accordingly this affection has been described as "thrombosis from marasmus," to distinguish it from infective or pyæmic thrombosis. It also occurs in cases of phthisis and chronic Bright's disease; in conditions of feeble cardiac power and liability to venous stagnation.

This rare disease is liable to be mistaken for several others which are comparatively common,—for the less acute forms of meningitis, for tumours, or for other lesions of the upper parts of the hemispheres.

Indeed, the clinical recognition of plastic or adhesive thrombosis of a cerebral sinus is rarely possible. Some writers have described engorgement of veins running from the anterior fontanelle of an infant to the neighbourhood of the temples and ears, and the occurrence of epistaxis, as signs of plugging of the longitudinal sinus; and œdema over the mastoid process as pointing to obstruction in the corresponding lateral sinus.

A curious case is reported by Dr Hyslop from the West Riding Asylum, of a woman suffering from acute mania, who lost all her symptoms for a period coincident with the appearance of hæmatoma of the ears and œdema of the mastoid region and of the orbits. Temporary plugging of the sinuses was diagnosed ('Brain,' April, 1886, p. 90).

The duration of the thrombosis is variable; it may last several weeks, or death may occur a few days after its commencement, so far as this can be determined from the clinical history of the case.

Its *treatment* would probably consist in keeping the patient in a state of perfect quietude, and perhaps in administering ammonia. In one remarkable case, the late Dr Moxon believed that salicylate of soda was of the utmost benefit.

Infective thrombosis of the sinuses.—Far more common than the last-described condition is one of purulent septic thrombosis of the sinuses.

This is always secondary, the thrombus is soft and readily detached, and the endothelium is rough and swollen. Anatomically it has the same relation to the last lesion as septic phlebitis has to adhesive inflammation of a vein, and it is as dangerous as the same process elsewhere. Putrefactive bacteria are always present.

It is most commonly the result of otorrhœa, with caries of the petrosal bone, but sometimes follows compound fractures of the skull, or caries of the bones of the nose or other parts.

It may lead to cerebral or cerebellar abscess, or to meningitis; or the septic phlebitis may spread from the lateral sinus down the internal jugular vein and produce purulent lobular pneumonia on that side, or general pyæmia.

Dr Pitt found 36 cases recorded at Guy's Hospital in the twenty years, 1870 to 1889. They were all secondary: 22 were due to septic suppuration of the ear; 7 followed fracture of the skull, and 3 carbuncle of the face; only one (a case of pyæmia) was caused by a distant lesion.

In 15 of these cases there was also lobular pneumonia; in 4 general pyæmia; in 3 abscess of cerebrum (1) or cerebellum (2); and in 5 meningitis.

He found the most frequent seat of intra-cranial thrombosis (whether simple or septic) to be the lateral sinus (36 cases out of 44), next the longitudinal (12), and next the cerebral veins (7). The other sinuses affected were the cavernous (4), circular, and superior and inferior petrosal.

This condition can only be recognised when local symptoms of the primary disorder, such as otorrhœa or tenderness over the mastoid process, give a local interpretation to the general signs of intra-cranial disease—severe headache, vomiting, and optic neuritis. The temperature is irregular and often very high, seldom normal as in cases of cerebral abscess. Rigors are usually present.

Treatment.—In such cases the mastoid bone should be trephined, and a suppurating lateral sinus may thus be reached and opened. With the happy audacity of modern surgery, this has been repeatedly performed, and a patient's life has been sometimes saved. Moreover, to prevent extension of the septic phlebitis down the internal jugular vein, that vessel has next been ligatured, opened, and washed out; and, lastly, the upper segment has been fastened to the surface of the neck, so as to give free external exit to the products of inflammation in the skull. Mr Lane had a successful case of this kind in a boy ten years old, in August, 1888; and while these sheets are passing through the press, Mr Ballance, of St Thomas's Hospital, has brought before the Medical Society of London, March 31, 1890, four similar cases, two of which were brilliantly successful.

HÆMATOMA OF THE DURA MATER.*—There still remains to be described an affection of the cerebral membranes which, having for many years been a puzzle in pathology, has recently become a subject of clinical interest also. It consists in the presence of one or more membranous layers on the inner surface of the dura mater, within the so-called arachnoid cavity. When recent they are soft and vascular, but in course of time they may become tough, white, and fibrous, so as to resemble in appearance the dura mater itself. Virchow in one instance counted no less than six or seven

* *Synonym.*—Pachymeningitis interna hæmorrhagica.

lying one upon the other. They commonly extend over the greater part of one hemisphere or symmetrically over both. They adhere at their margins so as to form a closed sac, or a series of sacs, which are generally attached much more firmly to the inner face of the dura mater than to the outer surface of the pia. In consequence they were formerly supposed to be formed by a separation of the imaginary parietal layer of the arachnoid from the dura mater; but this notion has long ago been refuted. Indeed, the cyst is sometimes perfectly unattached, so that it falls out as soon as the fibrous covering of the brain is cut through. A considerable quantity of blood, either recent or tawny-brown with age, is commonly found between the layers, which themselves are often deeply stained with hæmatoidin. But sometimes that which fills the adventitious cavity, or cavities, is a thin serous fluid which may contain a quantity of cholesterine; it is believed that such cases are the only examples of what was formerly described as *Hydrocephalus externus*.

In 1845, Sir Prescott Hewett, in a paper read before the Royal Medical and Chirurgical Society, maintained the opinion, which had before been promulgated by Houssard and Baillarger in France, that the starting-point of this disease is an effusion of blood. But a few years afterwards Virchow gave the powerful support of his authority to a very different doctrine (previously upheld by Bayle and by Hodgkin), namely, that the earliest morbid change is an inflammation of the dura mater; this, he supposed, becomes hyperæmic, and exudes upon its under surface a delicate material, richly supplied with wide, thin-walled vessels, which rupture and yield the blood that is so commonly found extravasated. Virchow's view has been adopted by most of those who have since written on the subject; and his name, "pachymeningitis hæmorrhagica," has met with very general acceptance.

Huguenin has, however, reverted to the theory that the disease begins as a hæmorrhage. If his observations are correct, one can hardly escape from the conclusion which he draws; and in any case the best designation seems to be the old one of "hæmatoma of the dura mater," which leaves the question of its origin open. In a large majority of instances the affection is merely a complication of cerebral atrophy, whether senile, or due to chronic alcoholism, or associated with general paralysis of the insane. Now, Huguenin states that in a number of cases of general paralysis he has been able to trace what he believes to have been the earliest stage of a hæmatoma, in the presence of a soft layer of blood-clot, spread out over the convolutions, having its greatest thickness (2 mm.) opposite the parietal eminence, and gradually thinning off towards its margins. This substance comes away from the dura mater in shreds, and has no vascular connection with that membrane. Moreover, the microscope shows that the clots contain at this period nothing but a network of coagulated fibrin, blood-discs, and leucocytes. Afterwards the clot undergoes organisation, vessels are developed in it, and become continuous with those belonging to the dura mater, which now looks more or less injected. Subsequent changes lead to the formation of thick membranous layers, with accumulated blood or serum between the layers.

The most usual seat of hæmatoma of the dura mater is over the upper surface of the hemispheres, corresponding to the dura lining the parietal bones. In about half the recorded cases it has been bilateral.

The original source of the hæmorrhage Huguenin believes to be in the veins which open into the longitudinal sinus; he has noticed that those

vessels are often varicose and thinned, that their coats are affected with fatty degeneration, and that they are sometimes filled with thrombi.

Hæmatoma of the dura mater occurs more often in males than in females. It is met with chiefly in those who are advanced in life, but exceptional cases of it may be seen at all ages; in 1864 Dr Wilks exhibited to the Pathological Society a specimen taken from a young adult. It is scarcely ever observed in the deadhouse of a general hospital; the specimen just mentioned came from the dissecting-room, the subject, a "half-witted" young man, having died in a workhouse.

There are enumerated among the causes of hæmatoma chronic affections of the lungs, heart, or kidneys, anæmia, scurvy, and hæmophilia, typhus, smallpox, and acute rheumatism. Injuries to the head seem occasionally to produce it. In 1855 Dr Quain showed to the Pathological Society a specimen taken from a farmer, aged fifty-eight. He had for three years suffered from various cerebral symptoms, which dated from a fall from his cart, when he received a large scalp wound, and was for a time insensible.

Excessive anæmia, particularly Addison's anæmia gravis, and chronic alcoholism, appear to be the best established predisposing causes. Whooping-cough is an exciting cause, as can be readily understood.

The clinical course of hæmatoma of the dura mater varies widely in different cases. Sometimes the only symptoms are a fatal apoplectic seizure, consequent on the sudden outpouring of a large quantity of fresh blood in or between membranes formed out of a coagulum of old date, which itself had in no way disturbed the patient. Very often the affection is found on *post-mortem* examinations of those who have died of general paralysis of the insane, without any unusual symptoms to suggest the presence of a hæmatoma. It would be a great mistake to suppose that the epileptiform and other attacks which are of frequent occurrence in general paralysis are usually, if ever, traceable to that condition. Indeed, as Huguenin remarks, the wasted brains of these patients allow of the accumulation of a large quantity of blood on their surface, without pressure. Even headache seems to be very generally absent in such cases.

Huguenin relates the case of an intemperate man, aged thirty-one, who about two years before his death began to complain of severe headache, and who one day fell down unconscious, with a slow, full pulse, contracted pupils, transitory convulsive movements of the right side, and partial paralysis of the right side of the face. After twenty-four hours he gradually recovered his senses and got up, but he continued to suffer from pain in the head, and slowly lost his memory and intelligence, and finally he had another seizure which proved fatal in four days. The brain was found atrophied, with dilated ventricles, and with a hæmatoma on each side consisting of a complete membranous sac divided into compartments.

That it is possible for hæmatoma to subside after giving rise to well-marked symptoms appears to be established by the following case recorded by Bouillon Lagrange, and quoted by Huguenin.

A man, aged seventy-five, who was suffering from drowsiness, and failing in memory and bodily activity, had a fall from his horse. Though not injured outwardly, he now became more deeply unconscious, with right hemiplegia. At the end of two months he was comatose and almost totally paralysed; he was unable to speak, and passed his motions under him. After this, however, he gradually began to improve, he regained his senses and his memory, he recovered the use of his limbs, and when two more

months had elapsed he was considered to be cured. He remained well for six months, and then he was murdered. On a *post-mortem* examination, besides a recent injury to the skull, the back part of the right hemisphere was found to be flattened by a cyst, which adhered to the visceral arachnoid and contained three or four spoonfuls of a bloody liquid.

Griesinger ventured to infer the presence of dural hæmatoma in a man, aged fifty-seven, who recovered and was in good health at the time when his case was published. He had been a spirit-drinker, and for about five months had suffered from severe headache, extreme drowsiness, and confusion of ideas. His gait then became unsteady, his pupils were contracted, his pulse was rather irregular, and there seemed to be slight paralysis of the left facial nerve. He would sleep all day long, and passed his urine in his bed; but at the end of a month he began to improve, and in about ten days from that time he was perfectly well. Griesinger confesses not only that he anticipated a fatal issue, but also that he expected to find a rapidly growing cerebral tumour. So little is positively known of recoveries from any organic disease of the brain, that the above observations of Griesinger and Bouillon Lagrange are well worthy of being remembered.

The best treatment for a case supposed to be one of hæmatoma would probably consist in the application of cold to the head, in the administration of purgatives, and perhaps in the abstraction of blood by leeches or by venesection.

Meningeal Hæmorrhage.—When blood is found effused into and under the pia mater the symptoms are those of cerebral hæmorrhage producing apoplexy or hemiplegia or both, and have been described in the chapter on that subject (*supra*, p. 557). The effusion is commonly large, the symptoms severe, and the fatal issue not long delayed. In a woman who was more than once under the writer's care with symptoms of mitral stenosis and embolism of the femoral artery, and subsequently of the radial, death followed about eight hours after a sudden attack of apoplexy, and meningeal as well as cerebral hæmorrhage was found after death (April, 1890).

Congenital meningeal hæmorrhage sometimes occurs during protracted labour from interference with the circulation. It may prove rapidly fatal; but when the infant survives, atrophy of the cortex corresponding with the hæmorrhage follows, and produces a remarkable clinical disease characterised by spasmodic movements, and described as congenital choreiform spasms (*vide infra*, p. 745).

GENERAL PARALYSIS

AND OTHER CHRONIC DISORDERS DUE TO DIFFUSED LESIONS OF THE BRAIN

"Quemne ego servavi in campis Gurgustidoniis,

GENERAL PARALYSIS OF THE INSANE—*History—Ætiology—Symptoms, stages and course—Anatomy—Diagnosis—Prognosis—Treatment.*
Other forms of cerebral atrophy—Senile—Alcoholic—Saturnine.
Chronic diffused inflammation of the brain—Hypertrophy of the brain.

IN 1860 Griesinger, in a paper in the 'Archiv der Heilkunde,' drew attention to the importance of distinguishing among organic affections of the brain those which are limited to some particular region (focal, *herdartig*) from those which are diffused. Of the diseases which he placed in the latter class, some, belonging to the membranes and ependyma rather than to the cerebral substance, have been described in the last chapter. But there remain others, which we will now discuss. As might be expected, they have no localising symptoms. Griesinger briefly sums up their effects as consisting of "giddiness, diffused headache, delirium, and mental failure—from slight dulness of intelligence up to imbecility,—drowsiness and stupor, tremors and involuntary quiverings of the muscles, vomiting, and, lastly, the more positive indications of augmented pressure within the cranial cavity, slowing of the pulse and of the respiration."

In the diagnosis two points have to be borne in mind: (1) that local affections may produce like symptoms if they happen to take up a large space, or if they are seated in a part of the brain of which no special function is known; (2) that diffused organic diseases are very apt to be confounded with certain neuroses, and with the various forms of insanity (*psychoses*), in which no anatomical change is present.

GENERAL PARALYSIS OF THE INSANE.*—With the exception of a slight reference in the works of Thomas Willis, the celebrated anatomist and physician, who died in 1675, the earliest mention of this disease seems to have been made by another Englishman, John Haslam, in 1798; but afterwards its study was taken up in France, and the first complete account was published by Calmeil in 1826. Of late years it has attracted much attention both in England and in Germany, but even Griesinger refuses it an independent position in the nosology, and describes it in a chapter on the complications of insanity. Yet we shall find that its symptoms and course are remarkably definite. It shows little

* *Synonyms.*—Dementia paralytica—Softening of the brain—Cerebral atrophy with delusions—General paresis.—*Fr.* Folie paralytique—Polyparésie—Délire des grandeurs.—*Germ.* Progressive Paralyse der Irren.

or no tendency to shade off into the other forms of mental disorder; it is not apt to come on secondarily in persons who are already the subjects of chronic insanity, nor does a relapse of mania or of melancholia ever assume its characters. It is, in fact, from the first distinguished more or less plainly by features of its own. The impairment of muscular power, too, is of a peculiar kind. The mere association of hemiplegia or paraplegia with unsoundness of mind does not constitute paralytic insanity. In 'Ziemssen's Handbuch' the article on this disease, which is written by Hitzig, is rightly separated from those on the psychoses proper, and appears among the organic affections of the brain. Perhaps the best name for it is that which he uses, "progressive paralysis of the insane," but in this country it is commonly called "General Paralysis of the Insane," or more briefly "General Paralysis." It constitutes a large proportion of the cases which in popular language are called "Softening of the Brain." Its importance may be estimated from the fact that in some lunatic asylums as many as one in four of all the male patients are said to suffer from it.

Ætiology.—The persons most apt to be attacked by general paralysis are married *men* in the prime of life. The proportion of males to females is variously stated by writers; some give it as eight or even ten to one, others as no higher than two to one. The women who fall victims to this disease almost all belong to the lower classes, whereas it is most common in highly educated men, with powerful frames and handsome faces, who have enjoyed life and lived hard. According to Mr Austin, general paralytics are (in England) fair-complexioned and thin-skinned, with blue or grey eyes.

The *age* at which it usually occurs is between thirty and fifty, particularly about the middle of that period. In persons over sixty it is scarcely ever seen, although Mr Austin refers to one instance in a man aged seventy-six. Those who live in towns and cities furnish a far larger proportion of cases than do rural populations. For this reason probably, the disease is rare in Ireland, in the Highlands of Scotland, and in Wales.

General paralysis, it is believed, differs from other forms of insanity in being less frequently due to inheritance or congenital predisposition; and if so, one would expect to be able to trace it to acquired conditions. But there is much difference of opinion with regard to its exciting causes.

Dr Blandford is strongly disposed to attribute it in most cases to sexual *excesses*. He admits, indeed, that he has not always been able to refer it to such an origin, but then, as he says, in married men there may be great difficulty in ascertaining the fact, and an amount of sexual intercourse which to some would be perfectly harmless may be injurious to others. Dr Sankey found that at Hanwell a large proportion of the women affected with general paralysis had led irregular lives. Griesinger attributes the disease to excessive mental excitement, especially to "emotional agitations." Austin says that it commonly follows a painful mental shock, such as would be caused by bankruptcy, or might arise from remorse. Hitzig believes that it results most frequently from the combination of hard work with venereal excesses and indulgence in drink.

It sometimes follows *injuries* to the head, or an acute febrile disease. Dr Savage finds it rare in epileptics, and frequent in those who have suffered from syphilis, as well as in subjects of tabes.

Symptoms.—The course of general paralysis is commonly divided into three stages.

(*a*) During the *premonitory period* an alteration in the character is the most striking symptom. Perhaps the man is extravagant in his expenditure, making presents to persons whom he scarcely knows; or he may be dull and sulky in his demeanour, or depressed and melancholy. So far there is nothing distinctive of this rather than of other forms of insanity; but there is commonly some impairment of memory. Dr Blandford says that such a patient is regardless of appointments, forgetful of the time of meals, of the hour for going to bed, and the like. He comes and goes, scarcely noticing those about him, giving absurd and conflicting orders to his servants, and falling into a passion if they are not instantly executed. He neglects his business, and is careless and indifferent to things which formerly interested him. When he takes up a new scheme his interest in it soon flags. He may commit indecent actions, but if he exposes his person he often seems to be half unconscious of what he is doing; or he perhaps commits assaults upon women, without regard to opportunity, place, or consequences. He sleeps ill, and drinks to excess from inattention, forgetting how much he has taken. He eats hastily, and is apt to spill his food on his dress. He is neglectful of his appearance, and his costume is often unsuitable for the occasion, or its different parts are incongruous. At this time there is no physical change detected by the physician.

Dr Savage notes, among early or premonitory symptoms, change of expression and of temper, perversions of the sense of smell, muscular fatigue, temporary aphasia, *petit mal*, and fits of unconsciousness or of convulsions without the characters of idiopathic epilepsy.

It is of the utmost importance that the distinctive characters of incipient general paralysis should be well known to the general practitioner, since he alone is likely to see the patient at this period of his disease.

(*b*) After a few weeks, or at the end of a month or two, the *second stage* develops itself, and the patient becomes manifestly insane. The *delusions* which he now exhibits are almost always connected with ideas of colossal size, or magnificent wealth, or extravagant numbers. He may say that he can walk 100 leagues in a day, or write 100 tragedies and 1000 poems in the same space of time, or that he is going to make his fortune by buying up all the joint-stock banks, or that he is about to marry the Queen and all the princesses. French writers give to this form of insanity the name of *délire des grandeurs*. These "large delusions" are not maintained from day to day, nor are they consistent with one another. In fact, in spite of his eager excitement, the patient's mental condition continues to be one of progressive decay. He is extraordinarily self-satisfied, full of ideas of greatness, importance, and riches; but he takes no notice of the fact that the palace in which he resides is really a mad-house, and that the great men who surround him are lunatics like himself. Thus he cares much less about being placed under restraint than other insane patients.

In some instances, however, the delusions are not all of such a kind. Dr Blandford mentions that one of his patients thought he was going to be arrested, that people were about to injure him, that they were maligning, and would rob him. Yet, although his symptoms so far resembled those of melancholia, this man was often cheerful and talkative; he was very vain of his appearance, and exceedingly fond of his food.

Though cases of general paralysis usually begin with maniacal excitement and "exalted" delusions, a certain number begin with hypochondriacal

fancies. It is common to meet with patients of the age and with the history common in general paralysis, who imagine that their bowels are obstructed; or that their body has become very small, so that the term "micromania" has been invented to contrast with "megalomania," the delusion of greatness and power. Beside melancholia, any other form of mental disorder may accompany general paralysis. A practical aid to diagnosis is the fact that, however depressed such patients may be in the earlier stage of the disease, they become fat and easy in mind afterwards.

This second stage of general paralysis is further characterised by certain physical symptoms, which must be carefully looked for. The earliest of them is commonly a defect of articulation, an indistinctness or *thickness of speech*, or a hesitation in the middle of a sentence, or a tendency to substitute for the proper word another of which some letters are the same. The tongue, when protruded, is *tremulous;* that is, it not merely shows a fibrillary tremor—which is often observed in persons who are in perfect health, if they are nervous or anxious—but it oscillates irregularly to and fro, and cannot be held quiet. Sometimes the lips are seen to quiver, as they do in persons about to burst into tears. Austin adds that the mouth is generally closed, that the lips are compressed, and that the upper one is straight, its natural curves being obliterated.

The *pupils* are almost always unequal, often small; and they are sluggish in their reaction to light and to accommodation.

In some cases the *gait* becomes tottering, the patient walks stiffly and does not lift his feet; he straddles, or shambles along, and stumbles over any obstacle in his path. The movements of the hands may also be impaired; Griesinger speaks of them as being "stiff;" objects are grasped convulsively, and suddenly allowed to fall. The late Dr Mackenzie Bacon noticed that an important indication of the disease at this stage is an alteration in the character of the *handwriting;* it becomes tremulous and uncertain; sometimes, too, words are omitted, or the same sentence is written over and over again, or the whole becomes an incoherent jumble. All these, however, are indications of mental rather than of bodily failure.

The *knee-jerk* is sometimes found to be absent; sometimes it is exaggerated. Irregularity in this function is often a valuable early symptom.

In almost all cases one or more "fits" occur during this period of the disease. These may be of various kinds; the patient may become comatose, with complete paralysis, anæsthesia, and abolition of reflex movements, and in such an attack he may die. Or he may be less deeply insensible, with loss of power affecting one side only. The paralysis is often transitory, disappearing in a few hours. Austin believed that seizures of this kind were often direct results of the accumulation of scybala in the large intestine, and that the administration of purgatives and enemata was efficacious in removing the hemiplegia. In some cases the fits are epileptiform, and these are often directly fatal, as in the case of a man, aged thirty-seven, who died in Guy's Hospital in 1855. Lastly, the patient may be attacked with convulsions without becoming insensible, or falling.

Persons affected with general paralysis in its second stage are exceedingly liable to *paroxysms* of rage and fury, surpassing in violence those that occur in any other form of insanity except paroxysmal mania (p. 773). Even in an asylum such patients cause unusual anxiety and trouble to those responsible for their safety, and all writers are decided against allowing them to remain

in the hands of friends or relations at this period of the disease. Dr Blandford remarks that these are the persons who sometimes get their ribs broken by attendants before they can be mastered. They make the most desperate efforts to escape; or they tear up their bedding and clothes and go about naked; and they are often filthy in their habits.

After a variable period, a week, or a month, or a longer time, these violent symptoms commonly pass off. The patient's condition may even improve so much that he is able to leave the asylum. The disease is then sometimes said to be cured, but all writers are agreed that permanent complete recovery is the rarest possible event, and almost all deny that it ever occurs. Dr Blandford says that he has known some persons affected with general paralysis who were able to live with their families, to spend their money without extravagance, and to write long letters without mistakes, detailing their travels and amusements; but he adds that he has not met with one case in which the patient was capable of work or business. The friends and relations of such persons notice a childishness and slowness of intelligence in them, and if they attempt to resume their former occupations they break down and have again to be placed in confinement.* In many cases no improvement takes place at any stage of the disease.

(*c*) In the *third stage* the patient's mental condition gradually passes into one of dementia, and his bodily state into one of complete paralysis. His notions of magnificence may continue a little longer, but his understanding and memory soon become altogether destroyed. Sometimes he sits and grinds his teeth for hours together. His speech cannot now be understood; his power of swallowing is greatly impaired. His hands tremble so that he can scarcely hold anything; and it is as much as he can do to shuffle about the garden with the aid of an attendant.

This stage leads up to a fatal termination, which is seldom long delayed. Writers are agreed that the average duration of the disease is short. According to Hitzig the majority of patients die in from fifteen to thirty months after their admission into an asylum. Calmeil and Griesinger speak of the ordinary course of general paralysis as lasting from several months to three years. But the last-named writer alludes to exceptional cases, in which life was sustained for as long as ten years; and Dr Blandford mentions particularly the case of a baronet of large fortune, on whom a commission of lunacy was held in 1858, when he was suffering from general paralysis, and who was alive in 1870. In his experience the average duration of the disease has been considerably longer than that stated by Griesinger. He remarks that persons affected with general paralysis are always more feeble in cold weather; during the heat of summer they may regain strength to a surprising extent, but with the first frosts they fall back, and are apt to sink.

The immediate cause of death is often something which may almost be termed accidental. Thus a frequent mishap is choking; the patient goes on filling his mouth without swallowing the food, until it gets into the larynx and trachea, or at least fills up the pharynx so as to obstruct the entrance of air. Persons suffering under general paralysis should always have their meat minced, and an attendant should be present at meal-times. Another way in which death occurs is by the supervention of bronchitis or congestive pneumonia; if overlooked at its commencement this may destroy

* The only exception to this rule that I have met with in my reading is a case related by Schüle ('Allg. Zeitschrift f. Psychiatrie,' xxxii).—C. H. F.

life in a few hours.* Bedsores sometimes seem to bring about the fatal termination.

Anatomy.—General paralysis differs from all other forms of insanity in being constantly attended with morbid changes in the nervous centres. This, indeed, is admitted by all observers, but unfortunately, when the question is that of defining accurately their nature, and of distinguishing them from those which occur under other conditions, there is by no means the same agreement. Some writers have laid much stress on the fact that the pia mater is often abnormally adherent to the convolutions, so that the cortical substance becomes torn and assumes a ragged appearance when one attempts to strip off the membrane. But in other cases there is an excess of fluid beneath the arachnoid, and the pia mater can then be removed more easily than from the healthy brain. Thickening of the arachnoid has now and then been noted, pachymeningitis and hæmatoma of the dura mater, or increased density and thickness of the calvaria. The absolute weight of the brain is said to be diminished; the ventricles are described as being of unusual size, and their ependyma abnormally thick.†

The ganglionic cells of the brain have been found affected with pigmentary degeneration. Hitzig says that this change is almost always present in a very large number of the cells; but he goes on to quote Westphal as having stated that similar appearances are observed in other cerebral diseases, and even under normal conditions, so that he is obliged to add that it is only the extent of the degeneration that can be regarded as peculiar to general paralysis. Less commonly, he says, cells are seen which are swollen and sclerosed; this seems to be in accordance with an observation of Dr Major's, who in one case ('West Riding Asylum Rep.,' vols. iii and iv) discovered what he describes as an hypertrophy of certain cells, these being abnormally large and furnished with an excessive number of branches. Some have thought that the neuroglia is increased both in the grey and in the white substance. In the latter, patches of degeneration have been observed, of the kind termed miliary sclerosis (Rutherford and Tuke).

In one case Dr Lockhart Clarke found the white substance of the convolutions full of little cavities, of round, oval, fusiform, or crescentic shape, and varying in size from that of a small pea or barleycorn to that of a grain of sand, so that the cut surface looked like Gruyère cheese, or crumb of bread. These vacuoles were doubtless analogous to those which have been described by Dr Dickinson in other diseases. Most of them are empty, but some contained the remains of vessels mixed with granules of hæmatoidin. Probably they all were originally perivascular canals.‡ Changes in the blood-vessels have been described by some observers as features in the morbid histology of general paralysis. The small arteries become dilated and tortuous, and present twists or kinks in their course. Their nuclei and those in the walls of the capillaries are found to have undergone proliferation. Granules of hæmatoidin may be scattered

* I know of one case in which the patient, a nobleman, had been for his usual drive in the afternoon, but in the evening was noticed to be out of sorts; on auscultation it was found that he had pneumonia, and next morning he died.—C. H. F.

† Some of the earlier observers, including Calmeil, described the cortical substance of the brain as of a peculiar violet-red colour; Westphal admits that it sometimes presents this appearance, but he says that in other cases it looks remarkably pale and faded. As he remarks, these variations probably depend on the mode of death.

‡ See some cases of this remarkable condition of the brain described by Drs Savage and Hale White, in the 'Pathological Transactions' (vol. xxxiv, 1883).

upon their exterior, and they may be affected with fatty degeneration or calcification.

Moreover, other parts of the nervous system, as well as the brain, present morbid changes. The state of the spinal cord has been especially investigated by Westphal, and he has found that its posterior and lateral columns are often extensively altered. In the former the appearances are generally those of grey degeneration, exactly like that of locomotor ataxy; in the lateral columns the appearances are those of chronic myelitis. It is not supposed that such changes arise by the extension downwards of a morbid process which had commenced in the encephalon, for Westphal could not trace the affection of the posterior columns above the commencement of the fourth ventricle, nor that of the lateral columns beyond the lower end of the crura cerebri. They must, therefore, be regarded as of independent origin. Indeed, it would appear that even the peripheral nerves fail to retain their normal structure. At least, the sciatic nerves are said by Dr B. Lewis ('West Riding Reports,' vol. v) to be smaller and softer than natural, and less rounded in form. And under the microscope he was able to detect atrophy of the nerve-tubules, with overgrowth of the connective-tissue elements.

Bonnet and Poincarré state that the sympathetic ganglia, especially in the cervical region, present constant morbid changes. Their nerve-cells are sclerosed and pigmented or destroyed. The discoverers of these appearances believe that they constitute the starting-point of the disease, and that its phenomena depend upon the resulting vaso-motor disturbances. But this conclusion is unjustified. The changes in question are probably not morbid in the strict sense of the word, but after childhood are almost constant degenerative changes (see Dr W. H. White's paper, 'Guy's Hosp. Rep.,' 1890).

Diagnosis.—This must be considered from two points of view. In some cases it is a question between general paralysis and the psychoses; in other cases between it and paralysis dependent upon chronic alcoholism, wasting of the brain, or other diffused changes in the nervous centres.

It is not generally difficult to say whether a patient is suffering from general paralysis or from *mania*, even at an early stage. But mistakes have sometimes been committed, from its being supposed that the presence of exalted ideas is characteristic. Thus Dr Blandford mentions the case of a gentleman who wanted to make a tunnel through the earth to the antipodes, and who thought that people might live a thousand years if they would bathe in beef-tea and beer, and that he should be able to pay off all the mortgages on his estate by assembling 10,000 persons in his park, having them photographed, and selling the photographs at five pounds apiece. But it was clear that he was not labouring under general paralysis, for he did not stutter, his memory was perfect, and (above all) he had had a similar attack some years before. The opinion was given that the case was one of mania, and that it might pass off; and the sequel proved the correctness of this judgment.

The exceptional cases of general paralysis in persons at an advanced age may be difficult to distinguish from those of *senile dementia*. The childish nature of the delusions in those who are suffering from senile dementia commonly lends aid to the diagnosis: that complaint is slower and more uniform in its course; it is less apt to be complicated with epileptiform fits, and any apoplectic attacks that may occur are much more likely to be followed by permanent hemiplegia.

Chronic *alcoholism* sometimes gives rise to a chain of symptoms so like those of the less marked forms of general paralysis that it may be impossible to make a diagnosis between the two diseases until one has watched the case for a little time.

Lastly, there may be a difficulty in distinguishing general paralysis from some affections of the spinal cord. There are cases in which an impairment of muscular power shows itself some months before any psychical symptoms develop themselves. It has even been a question whether the disease may not sometimes run its course without being attended at any time with impairment of the mental powers. This question is answered in the negative by alienist physicians; but one may fairly reply that those observers would have no chance of seeing such cases, supposing them to occur. It is in the wards of a general hospital that they must be looked for. Dr Wilks published in the 'Guy's Hospital Reports' (xvi, p. 194) an instance in which the patient's mind was unaffected while paralytic symptoms were well marked. But this patient had only been ill nine or ten months, and in all probability mental symptoms afterwards developed.

There is sometimes great difficulty in distinguishing general paralysis in its early stage from *tabes dorsalis*. Dr Wilks relates that two physicians—one an authority with regard to the former disease, the other with regard to the latter—had the same case shown to them, and that each of them pronounced it to be an example of the malady with which he was the more familiar. The explanation seems to lie in the fact that the two diseases are not infrequently present in the same individual at the same time. In Westphal's cases of grey degeneration of the posterior columns of the cord with general paralysis, he expressly states that the patients had presented the ordinary symptoms of locomotor ataxy. As far back as 1862 Baillarger published clinical reports of five cases of a similar kind. General paralysis is thus a sequel of tabes.

Dr Bristowe has published an important lecture on the occasional difficulties of diagnosis between General Paralysis and *Insular Sclerosis* ('Brit. Med. Journ.,' Jan. 1st, 1887).

The *prognosis* is unfortunately uniformly unfavourable, and is little affected by remedial measures. The course is rather rapid, varying from a few months to two or three years.

Treatment.—In the early stage of general paralysis confinement in an asylum is absolutely necessary. It is, indeed, a question whether it might not sometimes run a more favourable course if the patient were secluded at an earlier period than is usually the case. His friends and relations are but too apt to take him to the sea-side, or even to make him travel from place to place; whereas what his brain really needs is absolute rest. Among medicinal agents Dr Blandford speaks highly of tincture of digitalis in doses of ℥xv to ℥xxx every four hours. He says that it often soothes such patients wonderfully, and restores them from a state of noisy turbulence to one of comparative rationality. According to Hitzig the application of galvanism to the nape of the neck is sometimes of marked temporary utility; he also speaks favourably of iodide of potassium. The bichloride of mercury has been largely used, but without any good result. Dr Blandford lays stress upon the importance of withholding stimulants, such as brandy, while there is excitement; but he says that opium, morphia and chloral are often useful both in the early, and still more in the later stages of the disease. The same writer insists on the

value of tonics when the more acute symptoms have passed off, the tinctura ferri perchloridi and the other preparations of iron being particularly serviceable. Dr Crichton Browne published two cases in which the extract of Calabar bean in doses of a quarter to a third of a grain, continued for nine or twelve months, appeared to cure the disease ('Journ. of Mental Science,' 1875).

Other forms of atrophy of the brain.—In sharp contrast with the definite clinical course of General Paralysis, which disease is chiefly seen in asylums for the insane, there occurs in ordinary medical practice a precisely similar atrophy of the brain, attended with the greatest possible variety of symptoms, or even with no symptoms at all. Clinically, therefore, it is distinct, but anatomically it is identical with the malady just described. This fact has been generally ignored, although Dr Wilks published some observations in reference to it in the 'Journal of Mental Science' for 1864. But that it is not an infrequent condition is evident from notes of no less than fifty cases in which it has been found in the *post-mortem* room of Guy's Hospital within the last twenty years; and that number might be considerably augmented, for only the more striking examples were selected.

The wasting of the cerebral substance is characterised, not only by loss of weight, but also by an obvious shrinking. When the dura mater is turned aside, after the calvaria has been removed, the surface of the hemispheres may appear to be covered with a gelatinous substance, which, however, is really an accumulation of serous fluid in the meshes of the pia mater, and runs out as soon as the arachnoid is punctured, leaving the membranes collapsed and wrinkled. The convolutions are small, and they are separated by deep, broad sulci; the ventricles are often large, the ependyma granular, and the choroid plexuses have undergone more or less cystic degeneration. The cerebral substance itself is in some cases firm and natural-looking. But in other instances it presents patches of softening, either thickly scattered throughout the white matter beneath the convolutions or limited to the basal ganglia. In an old man of seventy-six, whose body was examined in 1876, the cut surface of the hemispheres showed smooth-walled cavities round the vessels, especially in the neighbourhood of the grey matter, so that it had an appearance like that of Gruyère cheese—exactly such as was described by Lockhart Clarke in cases of general paralysis (p. 685). When morbid changes of this kind are present, the minute arteries are, as a rule, diseased. Not unfrequently they are so thickened, and even calcified, that their cut ends look like so many bristles embedded in the brain. The membranes, too, are often thickened and opaque, especially over the hemispheres. It would be difficult to deny that these last appearances are indicative of chronic inflammatory change, rather than of mere atrophy; but they certainly occur where there is no other evidence of inflammation.

The causes of atrophy of the brain vary in different cases. Sometimes it seems to be a *senile change*, and it may then give rise to no obvious symptoms; the old man whose hemispheres resembled Gruyère cheese was said to have been perfectly clear in his mind. In other persons of advanced years, however, there is a more or less marked failure of both mind and body. They are eccentric or odd in manner, or demented. One patient, a woman, aged sixty-eight, who was brought to the hospital for a fractured

thigh, got out of bed, splint and all, and tried to walk about, with the result that the limb became gangrenous. Another, a man, aged seventy-four, who was taken in for bronchitis, showed no special cerebral symptoms, except that he passed his evacuations under him. Others again have been admitted for injuries due to attempts at suicide; a woman had thrown herself out of the window and fractured her spine, and a man had cut his throat. Probably many cases of this kind are indistinguishable during life from those of ordinary insanity, in which the brain remains perfect, so far as our means of investigation enable us to determine.

Cerebral atrophy is not confined to old people; cases occur in persons between forty and fifty years of age. Thus in 1867 there died in Guy's Hospital a man, aged forty-nine, who had been an accountant, but who for some time had been unable to do his work. His memory had failed, his speech had become uncertain, he wrote badly, and he misspelt his entries in a cheque-book. Afterwards his writing improved, but he formed his words very slowly. When speaking he would lose the thread of his discourse, and vainly clasp his head with his hands in search of what he wanted to say. For two or three days before his death he lay in a doze. At the autopsy patches of brown discoloration, breaking down in the centre, were found in each corpus striatum; the cerebral arteries were rigid and calcareous, and the kidneys were granular.

In some cases of this kind the disease advances to a fatal termination within a few months of its commencement; its diagnosis from other organic affections of the brain may then be impossible. There is often more or less complete paralysis of the limbs; sometimes convulsive movements or jactitations occur, and sometimes epileptiform seizures. Headache appears not to be generally a marked symptom; but in one patient it was exceedingly severe for the last six years of his life.

Cerebral atrophy is often the result of chronic *alcoholic poisoning*. A large proportion of those who die of delirium tremens have wasted brains; but there remain cases in which the brain is found apparently healthy.

Another cause of cerebral atrophy is *poisoning by lead*. In 1863 a compositor, aged thirty-four, died in Guy's Hospital, who had been admitted for colic, and who afterwards became almost totally paralysed; the convolutions of the brain were shrunken, the sulci were deep and contained an excess of fluid, the ventricles were unduly large. Chronic plumbism, as is well known, sometimes gives rise to epileptiform convulsions, which may be repeated at intervals, and followed by delirium and by a fatal coma. In cases of this kind the brain is commonly found wasted.

In a patient of the writer's, however, a woman, aged thirty-five, who died after eclampsia, obstinate vomiting, and other symptoms ascribed to plumbism, the brain and membranes after death were found perfectly normal, and weighing 42 ounces. No trace of lead could be found here, although it was abundantly present in the liver, spleen, and intestines. The patient had worked in a white-lead factory, and showed the characteristic blue line; she also suffered from colic and paralysis of the extensors of the hand.

CHRONIC DIFFUSED INFLAMMATION—*General sclerosis of the brain.*—If we consider how important a part in the pathology of the spinal cord is played by diffused chronic inflammation, it is remarkable that similar lesions

are hardly known to occur in the brain.* The author, however, made two autopsies in which cerebral sclerosis was found.

One of them occurred in the practice of Dr Wilks, who recorded it in the 'Guy's Hospital Reports' (Series iii, vol. xxii, p. 22). A girl, aged fourteen, was admitted, in 1876, for general failure of mind and body, which had been coming on for about a year. The earliest symptom was said to have been an attack of weakness and loss of sight, which came on one day while she was out on an errand. Soon afterwards she had two epileptiform seizures, which began with a scream. She generally lay quiet, with a vacant stare, making no complaints, but smiling when spoken to. She could evidently see, and the optic discs were normal, but the pupils were dilated. If asked what her name was, or any other simple question, she answered sensibly, but very slowly. When food was put into her mouth she would cease to chew without swallowing it, so that it lay there until removed by the nurse. She often vomited. She was unable to stand, and had very little power over her legs; even her arms were moved but slowly and feebly. Her skin appeared to be sensitive. A month before her death she tried to strangle herself, and was found with a towel tied round her neck. Towards the last she lay with her eyes open, making no attempt to speak beyond a slight motion of the lips. Her temperature ranged from a little below to a little above normal. Before death her extremities became remarkably livid; and large bullæ made their appearance on the feet, which looked as though gangrene were beginning.

At the autopsy a deep purple discoloration was seen over the feet and ankles, the cuticle was detached from the rete mucosum, and the deeper tissues were all infiltrated with blood. The calvaria was thick and heavy and very unsymmetrical. The membranes were a little opaque, and there was an excess of fluid at the base. Over the convolutions the pia mater was everywhere abnormally adherent, so that in attempting to strip it off one peeled away a thin granular-looking layer of the cortex, leaving a roughened surface. The brain was small, weighing only thirty-four ounces, and its substance generally was tough. The cortex was not obviously wasted, and the boundary line between the grey and the white matter was everywhere well defined. The ventricles were much dilated, but their ependyma was not granular, except in the fourth ventricle.

The other case, one of less clinical interest, occurred in 1878 in a child, eighteen months old, a patient of Dr Pavy's. Its illness was said to have begun with a fit at the age of four months, and from that time it had been subject, especially at night, to seizures, in which it would fight for its breath, and appear to be choking, but would afterwards lie insensible for three days at a time, taking very little food, and twitching at the corners of the mouth. Fifteen days before its death it had a fit more severe than any previous one. Eleven days later it was again attacked, and on the following day it was brought into the hospital. It then lay comatose on its left side with the corners of the mouth drawn down and constantly twitching: when it was moved over, its whole body would become rigid, and the twitching at its mouth was more marked. It appeared to have lost sensation in the left side. The temperature, at first 102·4°, rose to 103·8° before death, and the pulse became scarcely perceptible.

* Acute myelitis is, however, almost as rarely represented by acute idiopathic softening in the brain as chronic sclerosis of the cord by sclerosis of the brain. The various systemic diseases of the cord have also no counterpart in cerebral pathology.

At the autopsy the child was wasted, with a pigeon-shaped chest and rickety enlargement of the ends of the ribs and of other bones. The brain was pale on the surface. The meninges looked healthy; they were not at all thickened or opaque, but very thin and delicate, as is usual at an early age. On attempting to strip the pia mater from the convolutions, however, it was at once found to be abnormally adherent, so that a thin, uniform, superficial layer of the cortex peeled off with it, leaving a rough granular surface behind. The substance of the hemispheres also was indurated, cutting firmly, and giving sections with sharp resistent edges, but the most striking appearance of all was a discoloration of the white matter of the hemispheres, which had a yellowish tint. This was more obvious on the right side than on the left, and in the anterior and lateral parts of the hemispheres than in the posterior parts. It was also more marked in the prolongations of the white matter into the convolutions than towards the centre of the brain, and in some of the convolutions the limit between the white and the grey substances was ill defined. The grey matter itself looked natural. The ventricles were not dilated. The basal ganglia, the pons, the bulb, and the cerebellum were all of their natural soft consistence.

Portions of the affected tissues from each of these cases were examined after the most approved methods by Dr Savage, of Bethlem Hospital, and also by Dr Frederick Taylor, but no histological change could be detected, except possibly a slight excess of corpuscles in the interstitial neuroglia.

Dr Gee has reported two cases of general cerebral sclerosis occurring in children: in one, a girl of eleven, there was spastic paralysis, and after death the brain was found to be small and firm, with excess of leucocytes in the lymph-sheaths of the cerebral arteries; in the other, a girl of ten, there was right hemiplegia with indistinctness of speech, and there was found atrophy of the left hemisphere with general induration of the brain ('St Barth. Hosp. Reports,' vol. xvi).

HYPERTROPHY OF THE BRAIN.—It has long been known that in certain cases in which the head appears unduly large, so that the presence of hydrocephalus is suspected, a solid brain really fills the whole interior of the skull. Instances of this kind were recorded by Morgagni; and others in the early part of the present century by several French observers, among whom were Laennec and Andral. The condition has generally received the name of hypertrophy of the brain; but its nature and its relations to other diseases still remain among the most obscure questions in pathology. Virchow several years ago suggested that it consisted in an overgrowth of the neuroglia rather than of the nervous elements of the hemispheres. Sir William Jenner, not long afterwards, maintained that it was due to an "albuminoid infiltration" of the tissues, like that which he believed to cause enlargement of the liver and spleen in rickets; he regarded it, in fact, as one of the minor effects of that disorder. But it appears to be certain that the subjects of cerebral hypertrophy are not always rachitic.

Magnan is said to have minutely examined the structure of a child's brain so affected in 1874, and to have found it perfectly normal. D'Espine and Picot accordingly still describe the disease as a true overgrowth of all the various elements of the cerebral substance. This conclusion, however, we can scarcely accept, not only because of its inherent improbability, but still more on account of there being other lesions of the brain (*e. g.* "diffused chronic cerebritis" and "yellow softening") which are easily recog-

nised by the naked eye, but in which the microscope equally fails to reveal marked histological changes. Indeed, it is worthy of notice that in each of the two cases of which Andral has given full descriptions, the grey substance of the convolutions is said to have been undistinguishable from the white, while the medulla resembled a hard-boiled egg, and in some parts was harder still. How can such a condition be distinguished from sclerosis?

Dr Fletcher Beach, of the Darenth Asylum, kindly furnished the following notes of two among six cases of this affection that have come under his notice. He found that the white matter showed "a uniform granular appearance under the microscope, with nerve-cells scattered sparsely throughout. There were a number of leucocytes present. The increase in size was evidently due to the large amount of granular matter."

In each instance the size of the head was a conspicuous feature during life. In one, a boy aged sixteen, it measured twenty inches in circumference; in the other, a boy aged ten, the measurement was twenty-two inches. Its form was, in each instance, square, not, as in hydrocephalus, round.

Other points of distinction from hydrocephalus are that the enlargement is more marked just above the superciliary ridges than at the temples, the eyes are not so wide apart, and the fontanelle is often depressed instead of being full and elastic. This last character seems hardly to consist with the accounts which have been given of the dura mater bulging as soon as the skull was opened, and of the convolutions being flattened. Although the brain in the older of Dr Beach's patients weighed no less than sixty-two ounces, the subarachnoid fluid was increased, and the ventricles were rather dilated.

None of Dr Beach's patients presented any signs of rickets, but, as he himself remarks, it is possible that they may have been rachitic at an earlier period, since they were, with one exception, above the age of ten years when they came under his observation.

Clinically it would seem that hypertrophy of the brain is characterised by a more or less marked deficiency of intelligence, drowsiness, headache, and liability to epileptiform convulsions; the gait is sometimes slow and tottering, and the weight of the head may cause it to hang forwards, or may throw the patient down upon his face when he is walking.

Under favourable circumstances life may be prolonged for years. The disease often ends by some intercurrent pulmonary affection, or by the supervention of acute symptoms and coma which, in one of Dr Beach's cases, were due to acute suppurative meningitis.

With regard to treatment nothing is as yet known.

FUNCTIONAL DISORDERS OF THE NERVOUS SYSTEM

THE SPASMODIC NEUROSES

WE have now completed the survey of those diseases which can be more or less certainly associated with organic lesions of the nerves, the spinal cord, or the brain. We have said nothing of diseases of the "sympathetic system," because, in the first place, the nerves and ganglia so named are not independent, but form part of the spinal system; and because, in the second, there is no evidence of any clinically recognised disorder depending on derangement of the "sympathetic" nerves and ganglia.

There remain the Functional disorders of motion, sensation, and intelligence, for some of which perhaps a special morbid anatomy is yet to be discovered; while others in all likelihood depend, not on lesions which can ever be distinguished by the scalpel or the microscope, but on nutritive disorders which pervert action without perceptibly altering structure.

We found it desirable to have regard to clinical characters even in the arrangement of organic diseases; and, in our ignorance of the causes and nature of almost all functional disorders, we have no choice but provisionally to classify them by their symptoms and course.

The first group of Neuroses may be termed Spasmodic,* for all of them are marked by spasms or cramps in the voluntary muscles.

FACIAL SPASM.†—This is a disorder for which we have no distinctive title in English. Dr Sieveking, in translating Romberg, introduced the term *histrionic spasm* as an equivalent for the German name, but it does not carry its meaning with it, and has not been generally accepted.

Its essential feature is the occurrence, at longer or shorter intervals, of a sudden and rapid involuntary contraction in a single muscle or group of muscles. One eye may be instantaneously closed and opened, or the forehead may be wrinkled on one side, and as quickly made smooth again; or the angle of the mouth may be twitched to one side, so as to cause a meaningless grin. Or, again, the head may be made to nod forwards, or the neck may be distorted to one side, or the shoulder shrugged, or the diaphragm may contract and cause the utterance of a sharp cry.

The person himself is often unaware of the complaint, which is, indeed, scarcely more than a morbid habit or trick. Trousseau says that he was consulted by a lady whose three daughters had muscles in different parts of the body affected with spasmodic tic, for which she found great fault with them, without knowing that she herself had it in her face.

Another point which this writer mentions is that the movements sometimes shift from one part and attack another. Thus a patient came to him for violent spasms of the head and one shoulder: methodical gymnastic exercises were prescribed; and after some time the affection disappeared from the affected shoulder, and presently showed itself in the other. A similar instance is related by Sir Thomas Watson, of a gentleman who when young used to give an involuntary shake of his head: a blister, applied to his throat for some affection of the air-passages, made this movement painful, and the movement ceased; but, to use his expression, it broke out in his nose, so that he was ever afterwards in the habit of wrinkling it. A boy, aged twelve, four years before the author saw him, had acquired a trick of sniffing and coughing, as though he would be choked; this was followed after two years by a habit of "making faces;" and a month before he was examined he began to toss his head over to the right side at intervals of a few minutes, whereupon the sniffing and coughing stopped.

Sometimes, however, an affection of this kind lasts for a whole lifetime unchanged. Trousseau mentions that after the lapse of twenty years he recognised a former schoolfellow, who happened to be walking behind him, by a sort of barking noise that he made.

It does not appear that these histrionic or pantomimic spasms are ever influenced by treatment, but probably they might be corrected when they first appear in children, in the same way as any other bad habit. The application of the continuous current to the portio dura is, however, advised.

SPASMODIC WRYNECK.‡—Beside the form of spasmodic tic just mentioned, which consists in twitching of the patient's head to one side, the

† *Synonyms.*—Histrionic spasm—Clonic spasm in the area of the portio dura.—*Fr.* Tic convulsif—Tic non-douloureux faciale.—*Germ.* Mimischer Gesichtskrampf.

‡ *Synonyms.*—Torticollis—Tic rotatoire—Nickkrampf—Clonic spasm in the area of the nervus accessorius.

cervical muscles are liable to another kind of spasm, which is called "wryneck" or "torticollis." This is characterised by a rapid succession of jerking movements, which draw the head with great force towards one shoulder, and give rise to extreme deformity. When one sterno-mastoid is chiefly involved, the corresponding ear is pulled down towards the clavicle, while the chin is pushed upwards, and the whole face is thrown to the opposite side. When it is the trapezius, the head is drawn backwards, without rotation of the chin, the shoulder being at the same time raised.

One or more muscles in a state of powerful contraction can generally be felt, or even seen, through the skin.

Ætiology.—Spasmodic wryneck occurs chiefly in adults. Dr Reynolds says that all but one of the patients whom he has seen have been more than thirty years of age, and the majority more than forty. However, one well-marked case has recently been observed at Guy's Hospital in a girl, aged eleven, who had had it ever since she was a baby. Men and women appear to be affected in about-equal numbers.

This disease is often directly traceable to cold. Thus Dr Golding-Bird ('Guy's Hosp. Rep.,' vol. vi) had a patient who was attacked shortly after having been thrown into a state of partial stupor by driving across an open country in a gig one severe winter's night. And Dr Bright relates the case of a woman who was sitting exposed to a draught of cold air, when she suddenly felt what she thought was "a nerve giving way" on the left side of her neck, whereupon her head was drawn to the right. We had two instances in which the complaint appeared clearly to be the result of a fall upon the head. Very often, however, no exciting cause can be discovered. The patient, if a woman, may have been pregnant when the complaint began, or it may have followed a severe mental shock or an attack of fever; but none of these conditions precede it often enough to be regarded as even predisposing causes. Dr John Harley has reported, in vol. lvii of the 'Med.-Chir. Trans.,' the case of an engraver, whose head was habitually kept raised and slightly rotated to the right, so that he might have an oblique view of the plate on which he was engaged. He also mentions the case of a governess, who spent much of her time in ruling the pupils' copy-books, and who used to rotate her head rhythmically and with emphasis from left to right; she, in her declining years, lost her control over this movement; and her face was twisted every second to the right shoulder, unless her attention was strongly engaged in some other matter.

Irritation from disease of the teeth is no doubt a cause of wryneck. In two such instances, however, the spasm seems to have been *tonic*. One is Mr Hancock's case ('Lancet,' 1859, i, p. 80) of a girl, whose head for more than six months had been drawn down nearly to the left shoulder; extraction of a stump and of a decayed tooth in the left side of the lower jaw completely cured her in a few days. The other case, which occurred in 1813, is related by Mr Mitchell in the fourth volume of the 'Med.-Chir. Transactions.' The spasms began in the tongue and side of the face, and only affected the neck after the lapse of some days; but precisely similar changes, in the extent to which different muscles are involved, occur in the ordinary clonic form of wryneck. The patient was a woman, aged fifty; during the attacks her neck was drawn round to the left shoulder, her arm was rigidly extended, her eyelids were widely opened, and the two eyes directed to the left; her mouth was opened and distorted to the left side, showing the clenched teeth; her tongue felt as hard as a board, and was

curved to the left side; her forehead was wrinkled, and all the muscles of her face were thrown into a state of rigid distortion. After three months the tonic spasm was succeeded by a rapid tremulous motion of the affected parts, and the attack passed off, to be repeated at intervals which rapidly grew shorter, so that a fortnight from the commencement of the disease the spasms became almost continuous. Extraction of some carious teeth and fangs in the left upper jaw was quickly followed by a cure.

Course.—In cases not directly traceable to cold, the development of the complaint is generally very gradual. Dr Reynolds describes the patient as at first feeling uneasy in his neck, and as thinking that something is wrong with his cravats or with the pillow, until after some months he discovers, or is told by a friend, that his head is not straight. During the early progress of the case, an ordinary observer might suppose that the man's shirt-collar was uncomfortable, and that he was trying to ease it by twitching his neck; or that he was trying to look over his shoulder. Pain is at first absent, but after a time he complains of a dull, aching sensation, which extends to the shoulder or down the arm. At first, by an exercise of the will, he can overcome the spasm, so as to look straight before him, or towards the affected side; even at an advanced stage he can sometimes by a very powerful effort restore the equilibrium of the two sides for a moment, but at the cost of much distress, and with the risk of aggravating the severity of the spasms afterwards. As the disease progresses, he generally gets into the habit of bringing his head into the proper position with his hands. Thus a patient used to walk about with his arm raised, and ready to seize hold of his nose, which he employed as a kind of lever to control the movements. The spasms are always arrested during sleep, and they often cease when the patient is in the recumbent posture, and when he supports his head with his hands. They are at once brought on by any excitement, or by talking, or by attempting to walk. In the more severe cases the head is jerked about with extreme violence, and this goes on for hours or even for days without any interval. Sleep is almost impossible, and the patient's state is one of the utmost misery.

Spasmodic wryneck may remain stationary for years, neither advancing nor receding. But sometimes it extends from the parts first affected to the side of the face and the eye, or to the shoulder and arm. In two cases at Guy's Hospital the movements began in the upper limb and afterwards attacked the neck. This, and the fact that the deep cervical muscles are sometimes the ones mainly concerned, prove that the disease is not specially associated with the sterno-mastoid muscle nor with the distribution of the spinal accessory nerve, as would appear from the description given by Erb and others. In some cases it passes off within a few months under treatment, and a long while afterwards returns with its characters unaltered. Thus in a case of Dr Golding-Bird's, already referred to, there was an interval of about seven years between the first and second attack; and in another case the patient got well, returned to his work as a gasfitter for thirteen years, and at the end of that time was again seized with the disease, but on the opposite side.

Wryneck does not appear, like spasmodic tic, to desert one part of the body in order to attack another immediately afterwards.

In the advanced stages of the disease, the muscles which are the seat of the spasms sometimes fall into a state of *tonic* contraction, so that for hours together the head remains obliquely drawn down to the shoulder but

perfectly motionless. Even then, however, any kind of emotional excitement, or the slightest attempt at voluntary movement, generally leads to the development of clonic spasms also.

Writers have described primary *tonic wryneck* as a separate form (*caput obstipum spasticum*), for in some cases there is no history of the occurrence of the ordinary jerking movements at any period. Thus a girl's head was drawn down so that the chin rested on the second left costal cartilage, and the right side of the lower jaw was so close to the sternum that it was difficult to introduce a finger between them. Very slight twitching movements were all that had been noticed, but the affection was said to have developed itself while the patient lay paralysed in bed, unable to move a limb, and this perhaps accounts for the absence of clonic spasms. The girl was the subject of well-marked hysteria, and probably the wryneck was of the same nature as hysterical contractions of the limbs.

Results.—One curious effect of wryneck when it occurs in childhood is the permanent deformity in the bones of the face to which it gives rise. In the case just alluded to the left side of the face was considerably larger than the right. When the girl's head was erect, the right eye lay at a higher level than the left one, the median line of the face, instead of being upright, formed an obvious curve, with its concavity towards the left, and the left side of the upper jaw projected beyond that of the lower jaw, while on the right side the relation between them was reversed. The vertebræ of the neck were also distorted, there being a projection on the left side, apparently caused by the transverse process of the atlas. Precisely similar deformities were noted in a little girl of eleven, who had been in the hospital a few years before. They are of importance, because they might be regarded as indications of primary disease of the vertebræ, such as often produces a prominence of the cervical spine on one side, and also causes impairment of the movements of the head.

Treatment.—This is very unsatisfactory: on the one hand many cases are altogether intractable and are not benefited by any curative measures; on the other hand those in which relief is afforded, or which get perfectly well, yield to the most diverse remedies, which must differ altogether in their operation; moreover, each in turn fails more often than it succeeds. Dr Reynolds speaks of galvanism as being very useful in cases which are not already of too long standing. He finds that a continuous current of moderate intensity, passed through the muscles which are the seat of spasm, causes them to relax, at least for a time. But he adds that even when by this means the head has been maintained in equilibrium for many minutes, day after day, he has often observed that, as soon as the poles are withdrawn, the spasms instantly return; and sometimes it has been obvious that the ultimate effect of the treatment has been to increase the movements. In a patient who some years ago came under Dr Habershon's care at Guy's Hospital a considerable amount of relief was afforded by the plan of fastening the sponges upon different parts of the neck, and leaving them for some hours at a time. Faradisation of the muscles on the opposite side of the neck is sometimes useful, by increasing their power of resistance. On the affected side there is an exalted sensibility by interrupted currents; the patient may be altogether unable to bear the application of one which is so weak as to cause no pain whatever on the healthy side.

Rest is of course essential; and it would seem desirable that some mechanical support should be provided which may keep the head in its proper position. Dr Reynolds, however, says that he has not yet seen any apparatus which a patient with confirmed wryneck could habitually wear, but that the appliance suggested by Dr Hearne, of Southampton, is useful in recent cases, by controlling the movements for an hour or two; as, for instance, when a clergyman wants to get through a service.

Another measure of which he speaks highly is the hypodermic injection of morphia. Beginning with a tenth of a grain, he recommends that one should, if possible, increase the dose until two or even three grains are administered twice daily.

In one case recorded by Dr. Radcliffe ('System of Med.,' ii, p. 133) arsenic was injected subcutaneously with very striking results. From five to fourteen minims of Fowler's solution were thrown into the connective tissue over the affected muscles at intervals of three or four days or longer; they caused much local irritation and inflammation; but this was afterwards diminished by diluting the solution with water. After the fortieth injection, at the end of about nine weeks, the patient left the hospital almost well. This method of treatment has, however, been tried at Guy's Hospital by Dr Wilks and also by Dr Moxon without success.

Dr John Harley has recently ('Med.-Chir. Trans.,' lvii) related two cases in which the administration of large doses of succus conii proved very useful. Beginning with an ounce of the liquid, he rapidly pushed the dose in each case until one patient took three and a half ounces once daily, and the other four ounces twice daily. The effect aimed at was the production of a general relaxation of the muscles, so that at the end, the second hour after swallowing the hemlock juice, the patient should be unable to rise from the sitting posture or to walk unassisted, and that there should be ptosis, impairment of power to masticate and swallow food, and slowness of speech. In the first case the spasm became greatly diminished; but the drug had ultimately to be discontinued on account of the mental depression to which it gave rise. In the second case the affection was almost cured, and the patient resumed his occupation, working half-time, with only an occasional tendency to a twist of the head if he became over-tired. Dr Moxon has followed Dr Harley's plan with a decided measure of success.

In a case recently in Philip Ward the constant galvanic current failed to do good, but the patient gradually improved under a mixture of bromide of potassium and arsenic, and went out apparently cured.

A severe plan of treatment, by which Busch succeeded in curing several cases permanently, is the application of the actual cautery to the neck on both sides of the spine, in lines five or six inches long; he kept up suppuration for some weeks after the separation of the eschars.

In one very severe case ('Med.-Chir. Rev.,' 1866) Mr Campbell de Morgan excised an inch of the trunk of the spinal accessory nerve, above the origin of the branches to the sterno-mastoid muscle, with permanent relief to the spasm, but with equally permanent paralysis of the affected muscles. Another operation which has been performed several times with good results is subcutaneous section of the sterno-mastoid muscle.

In those cases in which the spasm is tonic, it is advisable to straighten the head under chloroform, and to endeavour, by mechanical appliances, to prevent the return of the contraction.

FATIGUE-SPASMS.*—Within the last few years several observers have drawn attention to cases in which spasmodic contractions of various kinds are brought about by voluntary movement, the exciting cause in each instance being generally limited to some one particular action, so that the patient remains quiet when sitting or lying down, and is able to use all his muscles for other purposes perfectly well. One of the best papers on the subject is by Dr Weir Mitchell in the 'American Journal' for 1876. His name for this group of affections is that of "functional spasms;" but this might be taken as meaning "spasms which are functional and not organic," in which sense it would include all the diseases described in this chapter. "Function-spasms," "Movement-spasms," and "Fatigue-spasms," are terms which, if less euphonious, are also less misleading.

Many of Dr Mitchell's cases are exceedingly curious. Two are examples of what he terms "lock-spasm." A watchmaker, who often had to pick up and adjust very small screws, would find ten or twelve times a day that his thumb and forefinger suddenly became locked upon one of them, so that he had to release it with a loop of twine, not always without wounding the finger; even then the cramp would last for some considerable time longer. At a later period, when he was turning over the pages of a book, the finger and thumb would sometimes close with violence, so as to tear the leaf. Another man, a sawyer, was liable once or even twice a day to have the arm arrested, and fixed in a state of flexion at the moment when his saw was drawn back to prepare for the downward movement. By no effort that Dr Mitchell could exert was he able to overcome the spasm; on one occasion he made the patient bend over, so as to bring the forearm into a horizontal position, and he then found that for five minutes the biceps supported a weight of eighty pounds suspended from the wrist. Such cases are clearly analogous to the cramps of writers, pianists, telegraph workers and milkmaids (p. 702).

In other cases, the attempt to walk was accompanied by a tonic spasm of certain muscles, so that a kind of stringhalt was produced. Another patient, a journeyman tailor, had an extraordinary seizure whenever he jumped up suddenly from the prone or the sitting posture. The right leg was then bent at the knee, the left was thrown over it in violent flexion, the body and the head were twisted to the right, the right arm was extended and raised, the left was thrown outwards and backwards in extreme pronation. Then there was a general writhing of the whole frame, the facial muscles twitching here and there; and the attack passed off with a groan of relief. This man could make every possible movement, slowly or abruptly as he pleased, so long as he remained seated or lying down: he was even able to get up; and after cautiously standing still for a moment, could walk away as well as anyone else. Such cases resemble the saltatorial spasm to be presently described, and also the hereditary cases described by Thomsen (p. 712).

In other cases, again, spasms accompanied the act of laughing or talking, or, above all, chewing. One patient, as soon as he began to masticate his food, had his mouth jerked open, so that he had to keep shutting it with his hand. When he wanted to swallow, his face assumed an aspect of terror.

* *Synonyms.*—Functional spasms (Weir Mitchell)—Movement-spasms. This group includes most Reflex spasmodic neuroses, Saltatorial spasms and the Beschäftigungsneurosen of German writers, viz. writers' palsy, fiddlers', tailors', cigar-makers' cramp, lock-spasm, milkmaids' cramp, &c.

"He would suddenly muster courage, and swallow the contents of his mouth at a gulp. Then instantly the jaw flew open, the head was drawn back and down upon the left shoulder, the face was convulsed, and sweat ran from the forehead." In another case of the same kind the gastrocnemii were involved in the spasm, so that the patient was jerked into a squatting position. An instance came under the author's observation in which the chewing of food brought on a kind of wryneck, the head being twisted over to one shoulder; and another, in which the effort of speaking was attended with an extraordinary series of grimaces. These cases again are pathologically identical with the spasms brought on by handicrafts.

Saltatorial spasms.—Perhaps of all this group of spasmodic neuroses called forth by voluntary or reflex movements, the strangest are certain cases in which any attempt to stand excites violent convulsions. The patient is thrown off his feet, his legs pass into a state of clonic spasm, and he begins to execute a succession of the most rapid and irregular jumping and skipping movements, even though he may be supported on each side by another person. So great are his efforts that his face flushes, his pulse is quickened, and he breaks out into a profuse sweat. Yet when he is lying or sitting he remains quiet, and can move his legs perfectly well in all directions. For this affection a special name was invented in 1859 by Bamberger, who recorded in the Vienna 'Med. Wochenschrift' two cases of what he called "Saltatorial reflex-spasm, a remarkable form of Spinal Irritation." Dr Gowers described two cases of the affection ('Lancet,' July and August, 1877), with an analysis of the five previously recorded. In their details these cases differ to some extent from one another, and this affords an additional reason for including them under "reflex fatigue-spasms."

Sometimes it has been possible for the patient to excite the movements by pressing with his feet against the foot-board of the bed, even while he is lying down; in one instance, tickling the skin of the sole would elicit them; in another, pressure under a tender part of the spine had the same effect. They have often been much augmented by emotional excitement; and this has sometimes led to doubts as to their genuineness, it being found that they are much less violent when no one is looking on; but the same thing may be said of many other affections belonging to the same class. Erb suggests that saltatorial spasms will ultimately be found to be a kind of exaggerated tendon-reflex; but Dr Gowers found no ankle-clonus in his cases. No doubt the movements are due to the combined and simultaneous action of peripheral and voluntary stimuli upon irritable centres in the cord; but the same stimuli are in action in all healthy persons whenever they stand upright. In Bamberger's first case, that of a youth of nineteen, the affection came on during convalescence from acute pneumonia; recovery took place in about a month under the internal administration of morphia. Other cases have been much more protracted; in one instance the spasm had not subsided when the patient died of fever at the end of five years. There have been two cases in women, both of whom were affected with hysteria; one had several attacks of the spasm, each lasting some months; her recovery was once quite sudden, exactly as so often happens in hysterical contractures.

There is sometimes pain in the contracting muscles, sometimes none; there is no loss of power or of sensation.

The reflex arc does not appear to begin in the skin of the feet, but in deeper structures, probably in the tendon. It would therefore be analogous

to knee-jerk. In future cases the condition of this phenomenon and of ankle-clonus will no doubt be investigated.

The muscles of the trunk and head are sometimes affected, as well as those of the legs, but the arms escape.

This curious affection has been observed in both sexes, and at all periods of life, from childhood to old age. It appears to be sometimes associated with spastic paraplegia as a sequel of some form of myelitis. But most cases seem to be "functional," and occur with hysterical symptoms. What was called Chorea Major, or dancing madness, would probably in a sporadic form approach some of the cases of saltatorial spasm in young women. It has also relations to tetany (p. 707) and to post-hemiplegic chorea (p. 569).

Saltatorial spasms, once begun, may continue for months and years, or may return after disappearing. They do not appear to lead to further symptoms or to threaten life. No special treatment is known.

Other varieties.—Many other rhythmical spasms may be observed, chiefly in patients not suffering from organic disease. One variety is what has been called "Salaam palsy" (*Eclampsia nutans*), a habit of continually bowing the head as if making a profound reverence. It has been frequently observed in children. Similar spasms may affect the arms, as in a boy once in Guy's Hospital, under Sir William Gull, who was continually moving one arm up and down (*Malleatio*). The writer remembers a man who used, apparently without knowing it, to lift up one leg every third or fifth step in walking and strike it with the hand. Such a trick, again, has relations with such scarcely morbid and unconscious motor habits as Dr Johnson's of counting the posts, and the late Prof. De Morgan of touching the railings one by one as he went to college.

Clonic spasms may affect individual muscles of the face or limbs. When the eyelid of one side is the seat of the disorder, it has been named *spasmus nictitans* or *blepharospasmus*. Singultus or hiccough is a clonic spasmodic affection of the diaphragm.

Athetosis is the name given by Dr Hammond of New York to slow rhythmical clonic spasms of the hands. It has been already mentioned (p. 569) as an occasional sequela of hemiplegia.

Stammering and stuttering (*balbuties*) is due to laryngeal or labio-lingual spasm, or to both, and exhibits the same union of irregular contractions, with loss of power, and explosive completion of a co-ordinated function, which we have had occasion to notice in the whole group of which we are here treating. Some of these spasms are clearly reflex. Some resemble histrionic spasm, some saltatorial cramp, some hysterical movements, chorea major, and "ugly tricks" in children. Many are curable by discipline, or a shock to the imagination, or by growing out of them.

In some of his cases of function-spasm Dr Mitchell found benefit from the injection of solution of atropine into the affected muscles.

*Spasmodic affections caused by habitual handicrafts.**—There is a class of cases which evidently belong, pathologically, to the same group as the last, but which differ from the rest in the fact that the involuntary motions that attend them are only just sufficient to disturb the due execution of some

* There is no name which would conveniently include this group of spasmodic affections; that of "co-ordinated-business-neuroses," proposed by Benedikt, is somewhat unwieldy, and "occupation-spasms" does not seem quite right. "Handicraft-spasms," perhaps, might serve.

highly specialised action, involving numerous and complicated muscular movements, and that over-exercise of this action appears to produce the spasms. They are examples of voluntary "movement-spasms," of what Dr Poore calls "fatigue diseases."

A musician, for example, becomes unable to play the piano or the violin, whichever happens to be his instrument; a telegraph clerk cannot word Morse's machine; a tailor or shoemaker no longer has the power to sew; a milkmaid ceases to be able to press the milk from the cow's teats; a smith to bring down his hammer upon the anvil. In one case a man, whose whole occupation was to clean knives and boots and shoes for a large house, became completely incapacitated for his work, although he could still do everything else. Far more numerous are those in which the complaint consists in an inability to write, and this deserves special attention.

*Writers' cramp.**—The exact nature of the impairment in the power of writing varies widely in different cases of this disorder, so that hardly any two are alike. Sometimes the patient's complaint is that after he has been writing for a few minutes, his hand and forearm feel wearied; sometimes that the fingers become suddenly extended, so that the pen drops from his grasp; sometimes that the index finger is straightened and drawn off the pen-handle; sometimes that the fingers are pressed too tightly upon the pen, so as to impede its movements. In many cases there is no visible cramp or spasm; all that a looker-on can see is that the motions of the hand are arrested in the act of writing; but in other cases there is obvious shaking of the pen.

The handwriting is often altered in character; in some instances the change consists in a reduction of the size of the letters, the power to make free strokes failing, and the writing becoming "cramped;" other patients become unable to accomplish a "running hand," and are obliged to confine themselves to a slow "round text." The author had one patient who could write anything but shorthand perfectly well, but unfortunately he was a law reporter. In the great majority of cases, however, the peculiarity consists in an uncertain tremulous formation of the strokes which make up the letters. When the affection is severe the handwriting becomes illegible—a meaningless succession of shaky lines and curves.

Persons affected with writers' cramp adopt all sorts of odd devices. Some will write only with a quill, and, so far as it goes, this is undoubtedly a good plan, for the muscular effort required is much less than with a steel pen. Others employ a large, thick penholder, or fix a nib in a broad piece of cork. Dr Poore ('Practitioner,' xi) mentions the case of a man who used a rounded mass of wood of the shape of a boy's top, which he held tightly with the hollow of the palm of his hand. Others grasp a penholder with the closed fist, or fasten it to one finger by means of a ring.

Sometimes, however, the fault seems to be not so much in the hand as in the wrist and forearm. A patient of Dr Poore's said that the first thing he noticed was a difficulty in bringing down the hand upon the paper, and for three days he forced himself to write by holding down the right wrist with the left hand, but at last that resource failed him. Indeed, one of the most important characteristics of "writers' cramp" is that it is a progressive disease. For a time a person affected with it may succeed

* *Synonyms.*—Scriveners' Palsy.—*Fr.* Crampe des écrivains.—*Germ.* Schreibekrampf.—Penman's spasm—Mogigraphia (μόγις, with difficulty; γράφω, write)—Graphospasmus.

in accomplishing the art of writing by bringing different sets of muscles into exercise. Thus, instead of employing the weak muscles of the thumb and fingers, he may use those of the forearm; or he may place the arm in some extraordinary attitude as soon as he takes up the pen, resting, perhaps, his wrist upon the table, and raising his elbow at an angle; or pressing the limb close to the side of his body; or, again, straightening the elbow, and holding the instrument at arm's length. But if he persists in writing much all these resources soon fail him. The muscles which he has called in to his assistance "give out" in their turn. Even if he should have taken the pains to learn to use the pen with the other hand, that too is after a time attacked. At advanced periods of the disease the muscles are often affected with spasmodic contractions of considerable violence independently of all efforts at writing. Dr Poore's patient complained that his hand would sometimes bounce suddenly out of the side-pocket of his coat while he was walking in the street, and he once broke a jug in consequence of an unexpected spasm while he was pouring out some water.

In some cases the spasm extends to the muscles of the neck and body. Dr Reynolds mentions an instance in which the effort to write caused the head to be drawn downwards to the right shoulder and the trunk to be contorted, so as to be concave on the right side. The same writer also states that he has seen, in association with writers' cramp, torticollis, occasional strabismus, stammering, and palpitation of the heart.

There is not generally any impairment of sensation. Sometimes the patient complains of "numbness," or "tightness," or "coldness," or of some peculiar sensation which he cannot define in one particular finger, or running from some part of the hand up towards the arm. In some rare cases anæsthesia has been observed. Very commonly the act of writing, if continued for any length of time, causes the hand and wrist to ache, or even the shoulder or the spine. These abnormal feelings distress the patient to an extent which seems altogether disproportionate to that of the actual pain which he has to endure. Indeed, a peculiarity is often observable in the psychical state of those who are affected with writers' cramp in its more advanced stages; they are highly irritable and excitable, and very desponding about their complaint. Dr Poore speaks of one man as having been apparently on the verge of suicide, and of another as having actually taken up a knife with his left hand and stabbed himself on the wrist. Such patients are generally nervous, and they are less than ever able to write when others are looking on, or when the subject-matter is of special importance. Dr Poore was told by one person that he got on better when copying than when composing what he wrote; and another patient had to watch the point of his pen, for if he looked away from it his handwriting at once became unsteady. Those who are affected with this disease are also said to sleep badly, and to be ill-nourished, with soft flabby muscles. Dr Poore has often noticed a thin, brittle state of the nails.

Ætiology.—It is generally assumed that the cause of writers' cramp, and of the affections allied to it, is over-use of the muscles, or working too hard and too long at that particular kind of labour which becomes accompanied with the spasm; and it is undoubtedly true that most of those who are attacked are clerks, or accountants, or in some way professionally engaged in writing. Moreover, as Dr Poore points out, the commencement of the disease often dates from the time at which some heavy task has been accomplished, as when an architect has worked against time to

complete the details of a plan, or a lady to finish an etching for a bazaar. Yet some persons strain their powers to the utmost, and get through extraordinary amounts of writing, without suffering from scriveners' cramp; and others are attacked who have never written more than is safely accomplished by most persons. The author met with two such cases: one in a boy, aged fifteen, whose education seemed to have been rather neglected than otherwise; and one in a lady of fashion, who had at most to write a few notes to her friends. Dr Poore speaks of an instance having come under his observation in which three generations in a direct line were affected. Another of his patients referred the complaint to the severe shock caused by an alarm of fire.

Pathology.—The seat of this neurosis is doubtful. One theory, which is supported by Reynolds and by Erb, is that it lies in the central ganglia which effect the association and co-ordination of muscular movements for the more complex actions. The nutrition of these structures is supposed to be impaired as the result of over-exertion, and the consequence is a perversion of their functions, which expresses itself in irregular spasmodic movements. A strong point in favour of this view is the fact that when one arm has been affected the other is often attacked afterwards; and the relations which writers' cramp bears to torticollis and other spasmodic neuroses afford a further argument.

It seems more likely that the motor centres in the cortex are affected than those in the anterior cornua.

The other theory, which was first proposed by Zaradelli (1857) and is ably advocated by Dr Poore, is that the starting-point of the morbid change is exhaustion of some particular muscle or set of muscles—generally one of the small intrinsic muscles of the thumb or fingers—which are kept constantly in action throughout the whole time that a pen is held in the hand. One or more of these, it is suggested, begins after a time to respond sluggishly to the stimulus of the will. The patient then unconsciously calls into play other muscles, generally those of the forearm. In their turn these too become worn out, and thus the process of substitution is carried on, always with the same result. Dr Poore has in a large number of cases of writers' cramp tested the electric reactions of the muscles which are specially engaged in the act of holding a pen, and has found that often one or more of them showed a marked impairment of irritability as compared with those of the opposite limb.* It might be thought that a strong argument against the theory in question is afforded by the well-known and remarkable fact that a patient who is severely affected with the disease is often perfectly able to perform other actions. But Dr Poore argues that the utility of the affected muscles for other purposes is only apparent; the hand and forearm, he says, are so bountifully furnished that for most movements there are more muscles than are required. If a man finds some of them to be weak, he unconsciously substitutes others in their place to do the work required. This writer maintains that certain among the more delicate actions of the hand are generally interfered with beside those which give to the case its principal character. Thus one of his patients could no longer hold a knitting-needle; another was unable to take up her

* Electrical irritability is generally deficient, as Dr Frank Smith found to be the case in hammer palsy; but Dr Dubois, of Berne, has lately stated that in early cases of telegraph-workers' cramp faradic and galvanic irritability of the affected muscles is exalted, although afterwards depressed or lost ('Brit. Med. Journ.,' 1887, vol. i, p. 1302).

dress between her thumb and her forefinger; and a third could not toss over a letter into a letter-box. So, Erb states that the sufferers from writers' cramp may be unable to button their clothes, to work embroidery, or to play upon the piano. One of Dr Poore's patients had great difficulty in feeding and dressing himself.

Benedikt has proposed to distinguish a spasmodic, a tremulous, and a paralytic form of the disease.

Diagnosis.—The diagnosis of writers' cramp, or of the allied forms of handicraft and reflex spasmodic spasm, is tolerably easy when they have reached an advanced stage. But one must always recollect that impairment of the power of writing may result from a number of other affections of the nerves and muscles of the upper limbs. Progressive muscular atrophy, neuritis of the ulnar, the median, or the radial nerve, compression of either of these nerves by a tumour of whatever kind, may each give rise to this symptom. Dr Poore mentions a case of subclavio-axillary aneurysm in which the first thing noticed by the patient was that he could write only with great effort, and then illegibly.

As a rule, a person affected with writers' cramp goes on for a long time without medical advice, struggling against what he deems a foolish incapacity to carry on his duties. But when it does happen that one is consulted at a very early period, there may be great difficulty in determining whether the disease is really present or not. This is particularly the case if the patient is a nervous professional man, whose mind has for some time been dwelling upon the subject; or if he is a bank clerk, who has heard all about it from his fellow-officers, and who has perhaps been reading a number of medical books. Such persons come to one complaining that the act of writing causes a number of unpleasant sensations; and one may be in great doubt whether to laugh at their complaints or to take them seriously. It seems to me that the best indications are afforded by the effects of rest. If the supposed symptoms show themselves only at the end of a hard day's work, and are entirely gone the next morning or after the interval of a Sunday, they are not likely to be of serious consequence. Thus Dr Poore speaks of an eminent pianist who, after practising for a long time, found that he could not always strike the right note; but a few hours later he could play as well as ever. In such a case it is evident that nothing is seriously wrong.

Prognosis and treatment.—In most cases a right diagnosis is of the utmost importance, for on it may depend the whole future of the patient. At this period the discontinuance of all writing—or of whatever other action may be the exciting cause of the complaint—may completely cure it in the course of a month or two. Even then, indeed, there is always a risk that the disease may return if the muscles should be again overworked. But, most commonly, the prognosis that must be given is very unfavourable. At an advanced stage of the disease there is scarcely any chance of recovery, unless the patient can altogether give up his occupation for six months or even for a whole year. And in many cases treatment fails entirely, the disease advancing steadily in spite of all that can be done.

The only remedy appears to be galvanism. Of this Erb speaks highly, recommending the employment of ascending currents along the cervical spine, as well as peripheral galvanisation of the nerves and muscles specially concerned. But by far the best results have been obtained by Dr Poore. His method consists in making the patient perform rhythmical movements

with the affected muscles, while a continuous current of moderate intensity is passed through them. His first case was that of a man, aged thirty-two, who had suffered from writers' cramp for more than nine years, and in whom it presented its severest form. Dr Poore exercised separately the deltoid, the biceps, the triceps, and the other muscles, as well as those of the hands and fingers. When the treatment was commenced the patient could not finish writing the word George; at the end of five months he was able to write a whole epistle, forming his letters well and firmly. He had been unable to feed himself; he could now do all that he wanted, and had embarked in a small business. Another of Dr Poore's cases is little less remarkable. A man, aged forty, had for four years suffered from the disease, and had for six months been unable to write, the attempt to do so giving him great pain. After the first application of the current this pain disappeared, within a week he could sign his name with tolerable ease, and at the end of ten months his handwriting looked as good as it had ever been, although he was not at that time able to hold his pen quite properly and tightly between the thumb and fingers. Unfortunately, however, Dr Poore records no similar successes in his later papers on the subject.

Wolff's combination of galvanic treatment with massage is commended by Charcot, by Ross, and by de Watteville.

Dr Gowers strongly advocates free writing from the shoulder as a preventive and a remedy, and says that the disease is unknown among shorthand writers.

Bromide of potassium is said to be occasionally beneficial to patients affected with writers' cramp, by removing the depression and irritability from which they suffer. Strychnia is often injurious. Stimulating liniments and douches appear to be almost if not quite useless. Erb says that many patients are relieved by applying a narrow bandage or strip of plaster round the wrists. This cannot, however, be expected to do any good where the only muscles affected are the small muscles of the thumb and fingers.

*Hammer palsy.**—This curious variety of handicraft spasm was described by the late Dr Frank Smith, of Sheffield ('Lancet,' March 27th, 1869; and 'Brit. Med. Journ.,' Oct. 31st, 1874). He observed eight cases among the pen, blade, and file forgers, who use a hammer of three to eight pounds weight sometimes for twelve or thirteen hours, delivering as many as 28,800 carefully adjusted strokes every day.

The patient finds his hand has lost its cunning; he is awkward, and hits awry. Spasms of the flexors and pronators of the forearm appear, then gradual weakness of the whole limb, and finally muscular atrophy.

We lately had a typical case of hammer-spasm in Guy's Hospital (Philip Ward, No. 31, 1887) in a healthy, well-nourished man of twenty-seven. He worked at nail-making with a hammer of two pounds weight, and worked by the piece. His arm, on his attempting to move it, or on the hand being grasped, was at once thrown into clonic spasms, without pain, which affected the pronators and flexors of the forearm, and also the flexors and adductors of the arm. Sensation was perfect. There were no signs of affection of the cranial or other nerves, no wasting of muscles, and no cephalic symptoms.†

In Dr Smith's cases the right leg was frequently weak; there was

* *Synonyms.*—Hammer spasm—Hephæstic hemiplegia.

† This case, we afterwards found, was the same which formed the subject of a lecture by Dr Poore in the 'Lancet' for August 21st, 1886.

neuralgia or numbness, and painful spasm in the affected arm; sometimes ptosis or thickness of speech, while in one instance (No. 7) there was aphasia. Hence he proposed the name Hephæstic *hemiplegia.*

Of one case he writes: Neuralgia and an indescribable centripetal feeling frequently affected the right arm and forearm. The tactile sensibility of the forearm was almost lost; electro-sensibility and electro-contractility were almost extinct. Thermal sensibility remained. The temperature in the right axilla was 1° Fahrenheit below that of the left. There were no mental symptoms; sight, smell, hearing, taste, and speech were unaffected.

The facts of spasms being followed by paralysis, of extension of motor symptoms to the leg and face, and of the affection of speech, all appear to point to the motor region of the hemispheres as the seat of this remarkable disease. No autopsy has yet been made, and it is quite possible that the local lesion is, at least in its earlier stages, either vascular or otherwise unrecognisable after death. A "discharging," becoming afterwards a "destroying" lesion, would probably best explain writers' cramp and the allied spasmodic diseases. At least there seems less reason for placing the seat of the disease, whether "functional" or "organic," in the muscles, peripheral nerves, anterior cornua, or motor tract of the cord.

Some of Dr Smith's cases improved under sedatives and rest. In the case above mentioned in Guy's Hospital, Dr Poore's plan for scriveners' cramp was tried without benefit; also Calabar bean, bromides, and succus conii raised to a two-ounce dose, and continued three times a day for nearly a fortnight. Rest in bed seemed to be most useful, but the patient thought chloral hydrate at night not only gave him refreshing sleep, but made the spasms less severe during the day.

TETANILLA.*—In the spasmodic affections hitherto described the convulsive movements have been of a clonic kind. But there is one member of the group in which tonic spasm is the essential symptom. This is the disease to which Lucien Corvisart in 1852 gave the name of *tetanie:* previously it had been described by Dance in 1831 as "a kind of intermittent tetanus;" and Steinberg had called it "idiopathic" or "rheumatic contraction of the extremities." Trousseau's lecture on this curious affection first drew attention to it in this country, and Dr Moxon recorded a case in the 'Guy's Hospital Reports' for 1870. It differs pathologically and clinically from the terrible disease always known as tetanus.

Tetanilla is generally confined to the limbs, and affects chiefly their distal parts. Sometimes it is limited to the forearms and hands; much more rarely to the legs and feet. As a rule it involves all four extremities at the same time or alternately.

The patient first has a sensation of tingling in the parts which are to be affected, and then begins to find that their movements are no longer free. Soon the thumbs become forcibly adducted; the fingers of each hand are closely pressed together, and are half flexed at the metacarpo-phalangeal joints, but usually extended beyond; the palms are hollowed by the approximation of their inner and outer surfaces. Hence Trousseau's comparison to the conical form of the accoucheur's hand when introduced into the vagina to perform turning. The thumbs may be driven into the skin so

* *Synonyms.*—Tetany—Tonic cramps of the fingers and toes in children—Rheumatic contraction of the extremities—Remittent tetanus.—*Fr.* Tetanie—Tetanille—Contracture rhumatismale des nourrices (Trousseau).—*Germ.* Tetanie.

violently as to produce marks, or even (it is said) to give rise to sloughs. The wrists are half flexed, and the forearms strongly pronated. In the lower limbs the toes are bent down and adducted; the soles of the feet are hollowed, and the backs arched; the heels are pulled up by spasm of the muscles of the calves. The extremities are affected on both sides.

The contracted muscles feel hard; their resistance may be overcome by the employment of some force, which generally gives the patient pain, but sometimes relief. Thus the fingers and thumb may be straightened; but as soon as they are released they again become flexed as before. Another way of arresting the spasms is by means of cold. Trousseau mentions that persons in whom the lower limbs are affected can often regain the free use of them, for the time, by merely standing with naked feet on a stone floor; and the same result can be brought about by immersing the hands and forearms in cold water.

During the paroxysms the movements of the affected parts are much impaired. If, as is sometimes the case, the patient is a woman nursing a child, she cannot hold it in her arms. There is partial anæsthesia, so that the patient cannot judge of the size and hardness of objects. In walking he feels as if his feet were treading upon a thick carpet. Pain is sometimes altogether wanting, but it is usually present in more or less severity, and is compared to that which accompanies ordinary "cramps" of the legs. Another common symptom is that the backs of the hands and feet become œdematous, and sometimes red with swollen veins.

In from five to fifteen minutes the spasm generally passes off, but sometimes it lasts without stopping for an hour or two, or even longer still. As it subsides sensations of formication are again experienced.

After a variable interval another attack commences, and this goes on for several days, or sometimes for two or three months. Even after a long period of health the disease may return. A child, whose case is recorded by Dr Moxon, was first attacked by tetany when five months old, and had it on five distinct occasions, at intervals of from five to twelve months, before it reached the age of three years and a half. One of Trousseau's patients, a young man of twenty-one, had the disease every winter for four years, the contractions coming on every day during a period of two months.

Trousseau found that in a patient affected with tetany one can at any time bring on the spasms by compressing the principal nerve or artery in the upper part of the limb.

The electrical relations of the motor nerves and muscles in this disease have been investigated by Erb ('Ziemssen's Handbuch,' xii, p. 345), previously by Kussmaul and Benedikt, and more recently by Chvostek and Weiss, with the result that the excitability both to faradic and to galvanic currents has been found greatly increased except only where the facial nerve is distributed (see Dr Buzzard's observations, 'Clin. Lectures,' pp. 414, 417). We found in the two cases mentioned below that the closing contraction was apt to cause tetanus instead of an ordinary contraction.*

* The following summary of cases of tetany admitted into Guy's Hospital between 1866 and 1888 was extracted out of our clinical records by Mr Lefevre for the present edition:

1869. *Tetany.*—Boy, æt. 6: swelling of right foot, hot and tender; history of cramps *before* admission only. Relieved.

1870. *Intermittent tetany.*—M., æt. 3, with condition of talipes equino-varus. Relieved.

1872. *Intermittent tetanilla.*—M., æt. 18, with cramps in calves and hands; the diaphragm was also involved. Improved.

1873. *Tetany.*—M., æt. 2: hands cone-shape, feet extended; slight opisthotonos. Cured.

Cases presenting the characters just described are decidedly of rare occurrence; only seven have been seen at Guy's Hospital since the one recorded by Dr Moxon in 1870. One, in a boy three years old, was described by Dr Wilks in a paper in the same Reports for 1872, and in his lectures he recounts two others in youths of sixteen and eighteen. The former was a private patient; the latter was the third of the Guy's cases.

The writer had two boys, brothers, under his care within a few months, with the typical symptoms of tetanilla. One aged five, in Mary Ward, developed severe symptoms. The spasms became general, he lost his power of speech, and his temperature rose. After further local and general treatment he died, September, 1887, the illness having lasted about three weeks.

His elder brother, aged seven, was admitted into John Ward, November, 1888, with the same painful tonic spasms of his hands and feet. He slowly and gradually recovered, and at last went out well in February, 1889. In neither of these cases were there any clear signs of rickets.

In the present year (1890) we have had a ninth case in Mary Ward in an adult which resembled tetanilla in its localisation, and in being in all probability functional. A woman of about forty was suddenly attacked, as the result of strong and sudden emotion, by tonic contractions of her fingers and toes. This had lasted several months when she came under the writer's care, and two fingers of one hand had become contracted. The other hand was nearly well, and the toes could be flexed though with some pain. The case might be called carpo-pedal spasms in an adult. It had the character of an "hysterical" disorder.

In tetany the spasms are not always limited to the extremities. Trousseau describes instances in which the face and trunk were also affected. In these cases the face became distorted; the eyes acquired a squint; the sterno-mastoidei and the pectorales were rigid; the recti abdominis stood up like tense cords. The jaws were firmly clenched, and the speech was impaired. Laryngeal spasm sometimes occurred, causing lividity and apparent danger of suffocation. Febrile disturbance was also present. Yet even in such severe cases, the patient would often get up; and if an adult she would attend on other patients, although suffering from pains in the loins, and feeling bruised and exhausted. Sooner or later recovery almost invariably took place. Trousseau, however, mentions one instance in which death occurred from phthisis during a relapse of tetany, and another which was supposed to have ended fatally within a few hours of its commencement. Dr Moxon suggested that this was really a case of tetanus, but the hands and feet were characteristically affected; and these are the very parts which constantly escape the spasms of tetanus.

It appears likely that a very common affection is really a minor variety of tetany, namely, "*carpo-pedal contractions*," or "turning in" of the thumbs and great toes, which one looks for almost as a matter of course in rachitic children. Dr Jackson regards these as rudimentary epileptiform convulsions; but surely they are more closely related to tetany.

Notwithstanding occasional extension to other parts, tonic spasm of the fingers and toes is the distinctive feature of tetany, and this approximates

1876. *Tetany* (associated with rickets and diarrhœa).—Boy, æt. 6. Cured.
1883. ? *Tetany*.—Girl, æt. 10½. Right hand only affected; thumb flexed and adducted; fingers semiflexed; hand drawn to ulnar side. Rapidly disappeared.
1887. Boy, æt. 5. Hands and feet affected. Fatal by dyspnœa.
1888. Brother of above, æt. 7. Hands and feet, with much pain. Slowly recovered.

it to another affection of early life, *Trismus neonatorum*. It occurs in infants within a week after birth, and sometimes even in the first twelve hours. From Dr West's description of its symptoms it appears that, besides opisthotonos, there is clenching of the hands, flexion of the feet upon the ankles, and bending of the toes; and he goes on to say that "when the fit subsides the child still lies with its hands clenched and its thumbs drawn into the palm, the legs being generally crossed, and the great toe separated widely from the others." The head is thrown back, and the opisthotonos continues, although in a diminished degree. Before long the little patient becomes unable to swallow, and perhaps comatose; and death quickly ensues.

The frequently fatal result and the presence of opisthotonos seem to separate trismus neonatorum from tetany. But tonic spasm of the back of the neck is common in children with "carpo-pedal contractions."

The relation of these two affections to tetany is confirmed by their ætiology. The trismus of newly born children was at one time supposed to be a traumatic tetanus, excited by irritation which started from the umbilical cord. But that notion was refuted by the subsidence of the disease in the Dublin Lying-in Hospital, in consequence of the introduction of an effective system of ventilation. Previously, one in every six of the infants born there had died when less than a fortnight old; and nineteen deaths out of twenty were due to trismus. Afterwards the mortality was only one in fifty-eight and a half, and but a ninth part of it was from the disease in question. In the West Indian islands it is still common, and also in St Kilda; probably it is due to a vitiated state of the air in the lying-in chamber. In London it must be very rare, for Dr West saw only one case.

In a valuable paper in the 'Lancet' (May, 1887) Dr Cheadle relates a case of tetany in an adult, and remarks on the association of this disease with previous diarrhœa or lactation in women. He believes that rickets in infants is apt to produce various spasmodic affections, which sometimes take the form of infantile convulsions, sometimes of carpo-pedal contractions, sometimes of laryngismus stridulus, and sometimes, though less commonly, of tetany. Dr Eustace Smith and Dr Goodhart take the same view; and the latter writer quotes Mr Hutchinson's observation of the frequent coincidence of zonular cataract with infantile fits and rickets. Rickets has been present in most cases of tetany seen at Guy's Hospital.

Age and sex.—The majority of cases of tetanilla seen in England occur in children. In 142 collected from various sources Dr Gowers found 42 between one and nine years of age (and of these 34 under five), and 36 between ten and nineteen; making 78 under twenty, to 64 adults. Of the latter the majority were between twenty and forty (34 women to 13 men), 13 between forty and fifty (8 women to 5 men), and 4 (all men) above fifty. In children it is more common in boys than in girls. It occasionally occurs in families.

Trousseau speaks of tetany as occurring most frequently in women between the ages of seventeen and thirty, particularly in those who are suckling their children. One is tempted to think that there may be something in the diet adopted during the puerperal period by French physicians which lowers the health, and so brings on a disposition to the disease. Trousseau, however, speaks of it as being the direct result of exposure to cold. Tetany has been observed as a sequence after removal of the thyroid,—in seven out of seventy cases according to Wölfler. Trousseau also described diarrhœa as a frequent predisposing cause of tetany; he had also seen it

follow enteric fever and cholera. He had met with instances of it in women over forty years of age, and even in adult males.

Tetany sometimes occurs as an epidemic neurosis in girls' schools and in convents, as in the school at Gentilly in 1876. Such cases bring it into relation with hysteria, chorea major, and the extraordinary attacks of "convulsionnaires."

The immediate *pathology* of tetany is quite unknown; and it has no ascertained morbid anatomy. In the fatal case of the writer's referred to above, the brain and spinal cord were both normal to the naked eye, and after hardening and staining nothing abnormal could be found.

The malady has no connection whatever with rheumatism in any intelligible sense of the word; all that French and German writers mean by calling the contractures "rheumatic" is that they occasionally follow exposure to cold. Dr Hughlings Jackson suggests the hypothesis that cerebral influence is diminished, and that (supposed) cerebellar influence over the motor nerves is increased.

Dr Moxon remarked that the disease which has been called *spasmodic ergotism*, and which was prevalent in certain parts of Germany in the earlier part of the present century, was similar in its symptoms to tetany. Mr Wright's account of it ('Edin. Med. Journ.,' 1839) almost proves that the two disorders are identical, and that the former was not due to a specific poison, but to general deterioration of the health from a defective supply of nutriment. He states that in the eighteenth century a similar disease occurred in Sweden. (See also on this point a paper by Bauer in the 'Berliner klin. Wochenschr.,' 1872.)

The *diagnosis* of tetany is not difficult, spinal meningitis, especially epidemic cerebro-spinal fever (p. 653), being the only affection with which it is likely to be confounded. There is no rise of temperature in tetany, and when it occurs epidemically it is obviously a neurosis.

The *prognosis* is probably always favourable in genuine cases, but death may occur from general convulsions or other complications to which rachitic children are liable.

The *treatment* which Dr Moxon adopted in his case of tetany consisted in the administration of bromide of potassium in five-grain doses; in four days the spasms ceased to return, and the child afterwards took cod-liver oil and steel wine. There can be no question that such remedies are to be preferred to bleeding and cupping as suggested by Trousseau. Indeed, that writer himself makes an exception for weakly and debilitated subjects, for whom he recommends quinine with small doses of opium or belladonna; but cod-liver oil and good food are the best medicines. In severe cases he says that the inhalation of chloroform has sometimes given marked relief. He mentions a case which Aran cured by applying to the affected parts pieces of linen soaked in chloroform. Dr Wilks also finds cold applications the best. Internally chloral has been found most useful at Guy's Hospital.

Fresh air and exercise and moral discipline are probably the best treatment in many cases. In infants *chloral hydrate* (with or without bromides), followed up by good milk, cod-liver oil, meat juice, and other nutritious food, will in most cases cure by removing the cause as well as the symptom, in cases of tetany, or carpo-pedal contractions, or trismus. Dr Cheadle believes that Calabar bean will sometimes succeed in overcoming the spasms when other measures fail.

THOMSEN'S DISEASE.*—The first full and particular account of this remarkable affection was given in 1876 ('Arch. für Psychiatrie u. Nervenkr.') by Dr Thomsen, a Danish physician, who was himself, with several other members of his family, the subject of the infirmity. In the same year Seeligmüller published a characteristic case. Several others have been observed in Germany, France, Denmark, and Italy, and Dr Buzzard has recently described two cases in our own country ('Lancet,' May 14th, 1887). Erb published a monograph on the disease in 1886. A full bibliography was given by Dr Paul Chapman in the sixth volume of 'Brain' (April, 1883), and by Dr Hale White in the same periodical for April, 1886, and in the 'Guy's Hospital Reports' for 1890.

Symptoms.—The peculiar features of the affection are that when the patient endeavours to perform voluntary movement after rest, the muscles of the limbs when used are thrown into tonic contractions, which prevent motion and keep the parts in a state of stiffness, like that of cramp, though without pain. As in ordinary cramp, the contractions, though violent, are ineffective and irregular, portions only of the muscle being raised into bulging elevations. After a time the difficulty is overcome, and the patient is able to rise from his chair, and walk, run, or perform any action he desires with his limbs. But the difficulty returns again and again, so as seriously to interfere with his daily life. Seeligmüller's patient was a healthy young recruit, who found himself slow and awkward in performing his military exercises. Not only the arms and legs, but the muscles of the trunk, are subject to this difficulty, and also those of the tongue and lips, so that there results a kind of stammering—a violent effort to speak, inability to do so, and at last an explosive utterance, which passes into ordinary easy articulation for the rest of the sentence.

The involuntary muscles, as those of respiration and micturition and the sphincters, are quite unaffected. There is sometimes a feeling of numbness or "pins and needles" in the limbs, and occasionally pains, but these appear to be often absent, and never severe or long continued. There is no anæsthesia. The knee-jerk and plantar reflexes are usually reported to be present, and sometimes excessive; but in one of Dr Buzzard's cases the former was completely and the latter almost completely abolished. The galvanic and faradic irritability of the muscles is greater than normal, and they readily respond to mechanical stimuli, but contract and relax very slowly. The nerves react normally; there is no R.D. Fibrillary tremors have often been observed, and the contraction of a muscle after stimulation continues long enough to be photographed. Erb says that irritation of the ulnar nerve causes the muscles it supplies to contract, but Dr White finds that this may occur in healthy persons.

There is no atrophy of the affected muscles. On the contrary, they undergo true hypertrophy, especially, it would seem, the gastrocnemii, external vasti, glutæi, and trapezii, but always in a symmetrical manner. Yet the muscular strength of the patients is not at all proportionate to this apparently athletic development.

Some authors have described the mental faculties of the patient as deficient, but there seems no reason to regard this as a character of the disease, particularly since one of them taught us to recognise it. The patient is often intelligent and anxious to be relieved of his infirmity; but he says

* Called by Thomsen "Tonic contractions in voluntary muscles, as the result of inherited psychical predisposition." Strümpell and Erb call it "Myotonia congenita."

he feels awkward and unready; "before doing anything he must get his muscles ready," and hence he is incapable of prompt and rapid movement in reponse to the will. The general health is unimpaired.

We have lately had a typical case of this curious disorder in Guy's Hospital, in a healthy and well-made young Welshman. He was apparently strong, and of more than average intelligence, but he could not "start" walking or rising from a chair. A full account of his case is given by Dr W. H. White, 'Guy's Hosp. Rep.,' vol. xlvi.

Pathology.—No autopsy has yet been made in a case of Thomsen's disease, so that its seat and morbid anatomy are completely unknown. The primary change may be in the muscles or motor nerves, in the motor tracts of the cord, or in the cerebral cortex, or it is quite possible that there is no lesion discoverable by the scalpel or the microscope. Fragments of muscles have been removed by the "harpoon" (p. 498), and the fibres are found to be decidedly thicker than usual; the striation is unaffected, and there is no fatty or interstitial overgrowth as in pseudo-hypertrophic paralysis. (See the drawing in Dr White's article, pl. iii.)

Dr A. McL. Hamilton, of New York, and some other writers, have argued against the symptoms of Thomsen's disease being more than accidental or secondary. Dr Thomsen himself, as appears by the title under which he described it, regarded the affection as rather mental or emotional than organic in origin. The nervous centres have never been examined, for no patient has yet died.

Ætiology.—The reality of the disease as a recurrent combination of symptoms is established by its hereditary origin. Dr Thomsen saw signs of it in his own children while still in the cradle; his own mother was slightly affected, and two of her brothers typically so; of her thirteen children, six, besides Dr Thomsen himself, were subjects of the infirmity; and of his own five sons, four inherited it from their father. Benedikt, Leyden, Eulenburg, Pitres, Dalledet, Erb, all found the same hereditary and family distribution. It is more constant than in any other affection of the nervous system, except perhaps Friedreich's disease; but, like that rare and obscure condition, its duration is more extended laterally than vertically, *i. e.* it affects many brothers and sisters in a family, but does not so readily pass to the next generation, and rarely to a third.

Both sexes are liable to be affected, but males much more frequently. The disease is probably congenital, but the symptoms first become obvious when a boy goes to school and finds himself unable to take part in games, —in a case reported by Dr Banham, of Reading, only at the age of twelve.

Course and prognosis.—The symptoms do not appear to be aggravated after they are once fully developed, but there is no instance of their having disappeared, nor is any treatment even supposed to be efficacious. The condition is probably as innate and ineradicable as stammering, or timbre of voice, or tricks of speech and gesture; and, like them, if ever "grown out of" the result is not obtained by direct therapeutical means, but by the gradual effect of circumstances and of time.

PARALYSIS AGITANS.*—Unlike the preceding spasmodic disorders, the curious malady called shaking palsy has been known from an early period,

* *Synonyms.*—Shaking palsy—Paralysis cum tremore—'Parkinson's disease'—Scelotyrbe festinans—Chorea procursiva, senilis v. festinans—*Anglice,* The trembles.—*Fr.* Tremblement paralitique progressif.—*Germ.* Schüttellähmung.

though its true clinical features were only recognised by Parkinson in 1817. It consists in more or less violent oscillatory movements affecting especially the limbs, but sometimes the neck and the tongue also. It usually begins in one of the arms, and sometimes in a leg. Charcot says that it may for a time be limited to one thumb. The movement is at first very slight, a mere tremor; but gradually the amplitude of the oscillations becomes greater and the whole limb is involved, so that the patient is unable to go on with his work, and has to seek medical advice. Sometimes, however, the agitation of the muscles is severe from the very first. It is said to be sometimes the result of a sudden shock or terror, but in two cases under the author's care the patient went to bed as usual and woke in the morning with the disease fully developed, the right arm being in one instance the part affected, in the other both the left arm and the left leg. In two other recent cases at Guy's Hospital one side of the neck was the earliest seat of the movements. After a variable interval—generally after some months—the oscillations appear somewhere else, most frequently in the leg of the same side as the affected arm, but sometimes in the other arm. Presently the remaining limbs suffer in their turn. The head also begins to shake, and the tongue becomes very tremulous when it is protruded, or even when it is lying within the mouth; but nystagmus, or oscillation of the eyeballs, seems never to occur, nor do the jaws ever take part in the movements.

During the early part of its course paralysis agitans is almost always paroxysmal. Each attack generally lasts some hours, and it is followed by a feeling of great fatigue, which gradually passes off in the interval of rest before the next one begins. At a later period the movements become continuous.

The oscillations bear to voluntary motions of the affected parts a relation on which great stress has been laid by successive writers, but which is hardly so simple as has been represented. Mr Parkinson began his monograph by defining it as follows:—"Involuntary tremulous motion, with lessened muscular power *in parts not in action*, and even when supported; with a propensity to bend the trunk forwards, and to pass from a walking to a running pace; the senses and intellect being uninjured." He goes on to distinguish the disease from the tremor of old age, as well as from that caused by the vapour of mercury (cf. p. 521).

During the early period of the disease the hand may become perfectly steady when it takes up a tool or a pen, and the patient is able to control the agitated limb by an effort of will; moreover, the oscillations often go on without intermission when the elbow rests upon the knee. But at this stage the affection is usually dormant so long as the patient lies quietly on his back in bed, and it is certain that no movements occur during sleep except in the most advanced stage of the disease. Parkinson mentions that one of his patients had an intercurrent attack of right hemiplegia, in which the face was drawn to the left side, and this lasted a fortnight; during that time neither the arm nor the leg on the paralysed side was in the least affected with the tremulous agitation, but it returned as the limbs regained their power. In the later stage of shaking palsy the attempt to perform any voluntary movement brings on the oscillations with greatly increased violence. They are also much augmented by emotion or excitement. Even the presence of a looker on often affects such patients to a remarkable degree; a man who can write quite well when alone may be unable to form a letter while he is being watched by a clinical clerk. If

we hold the agitated limb, so as to check its movements, they are aggravated; and if we forcibly restrain them, similar movements appear in the opposite arm or leg.

Paresis.—According to most writers there is in paralysis agitans, beside the oscillatory movements, a certain degree of impairment in the muscular power of the affected parts. Eulenburg, however, has found that even in severe cases of long standing the reaction to induced or galvanic currents is perfect, and both Trousseau and Charcot have taught that the muscles really retain their full force. The former writer relates a case in which the patient was able to exert much more power with the affected hand (which, however, was the right one) than with the other, which was healthy—considerably more power than Trousseau himself could exert. But this must not be taken as showing that the disease had actually augmented the force of the limb, since it was not known what the man's strength had previously been. Another point observed in that case was that the contractility of the muscles was very quickly exhausted; when told to open and shut his hand in quick succession the patient at first did so rapidly, but after fifteen seconds more slowly, and soon not at all. Charcot further remarks that there is often a retardation of the influence of the will, shown by an unduly long interval between a thought and its expression in words.

Recently M. Bourneville, the editor of 'Charcot's Lectures,' has made observations on six patients with the dynamometer, which appear to show that their strength was really diminished to a considerable extent.

In most cases limbs affected with paralysis agitans have their cutaneous sensibility unimpaired. Charcot, however, says that a feeling of pins and needles in the hands and feet is sometimes complained of; this was the case in a patient of the author's, who also said that he was unable to feel the ground. Headache and vertigo are not uncommonly present; and at an advanced period of the disease there may be loss of memory, and even delirium.

Tonic spasms.—One impediment to voluntary movements in the more advanced stages of paralysis agitans is the occurrence of *rigidity* in the muscles of the affected parts. Charcot has pointed out that the patient commonly maintains an attitude which is characteristic of the disease. The head is bent so that the chin approaches the sternum, and he can with difficulty raise or turn it to left or right. The body is almost always bowed forwards when he is standing. The elbows are generally drawn slightly away from the chest, and partially flexed; the hands present a deformity somewhat like that which occurs in osteo-arthritis, the three inner fingers being inclined towards the ulnar side of the hand, while the thumb and forefinger are stretched out and brought close together as in holding a pen. In the lower limbs the rigidity is sometimes very marked; they are semi-flexed, the knees are brought together by a movement of adduction, the feet are curved inwards as in talipes equino-varus, and the toes are arched like the three fingers.

Articulation is unimpaired until the last stage, but the speech is slow and jerking, as though a considerable effort of the will were needed for the pronunciation of each word. Charcot compares it to a bad rider trying to talk when mounted on a high-trotting horse.

The way in which the head and body are bent forwards in the more advanced stages of paralysis agitans accounts for a symptom which Parkinson noticed, namely, that the patient tends to fall upon his face when he attempts to walk, and that his steps are consequently hurried, so that he

runs instead of keeping to his ordinary pace. This had, indeed, been previously described by Sauvages, but as a separate complaint, under the name of *Scelotyrbe festinans.** The man has been said to be constantly trying to overtake his own centre of gravity. Parkinson mentions a case in which an attendant was obliged to walk backwards in front of the patient with one hand on each of his shoulders to prevent him from falling. When he first gets up from his seat, which he does very slowly, the patient makes a few hesitating and ineffectual steps before he seems to be able to start off, and in walking he treads only upon his toes, being unable to bring his heels to the ground. But the most remarkable symptom is that some persons affected with paralysis agitans walk backwards without intending it and when they mean to go forwards. Some years ago a striking instance of this occurred at Guy's Hospital. The patient, after a few ineffectual efforts to rise from his chair, would stand up, pause, make two or three abortive attempts at starting, and then succeed in walking a few steps towards the door, when suddenly he found himself hurried against his will backwards into the umbrella-stand in the corner of the room. It was like the sudden reversal of the engines of a steamboat. Charcot met with a case in which he could at any time induce such retrograde movements by unexpectedly giving a gentle pull at the patient's dress when she was standing up, and Dr Buzzard remarked exactly the same thing in an elderly woman, whose appearance and symptoms he graphically describes in his lectures. The movements cease during sleep, except in the latest stages.

In the more marked cases of paralysis agitans the movements of the hands are not merely oscillatory, but are to some extent co-ordinated. The finger and thumb move as if the patient were rolling a cigarette paper, or crumbling a morsel of bread.

Profuse sweating is an almost constant symptom when the oscillatory movements are at all severe. The patient may become so bathed in perspiration as to have to change his clothes many times a day. He often suffers greatly from a feeling of heat, especially about the epigastrium and in the back, so that he insists on being kept lightly covered. But with the thermometer the temperature is always found to be normal.

The features are immobile, and the face has a remarkably impassive expression. The voice is often shrill and piping. Dr Buzzard believes that this change of an old man's voice to "childish treble" is an almost decisive symptom of shaking palsy.

Pathology.—It is still uncertain whether paralysis agitans should be regarded as an affection of the brain or of the spinal cord. Parkinson supposed its seat to be in the cervical region of the cord, extending up to the bulb. But perhaps indications adverse to such a view may be found in the fact that after one upper limb the corresponding leg is generally next affected, rather than the opposite arm; and still more in the cessation of the oscillations during sleep, and throughout the continuance of a hemiplegic attack, so far as the paralysed limbs are concerned. Hitherto anatomical observations have thrown no light on the question. The author made one autopsy, on a woman, aged forty, who died of phthisis after having suffered from paralysis agitans for eight years; for a year her speech had been impaired, and at last it was unintelligible. The only unusual appearance detected was that the substance of the pons towards the floor

* Σκελοτύρβη (disorder of the legs, staggering) occurs in Strabo, Pliny, and Galen. The term has been also applied to chorea.

of the fourth ventricle looked unduly grey. Westphal and Wilks also failed to find any lesion. Slight thickening of the cortical layer and reticulum were found by Cayley in the cord of a patient of Murchison's, aged seventy-one, who died of typhus after being twelve years the subject of paralysis agitans ('Path. Trans.,' 1871, p. 24). Charcot has been able to examine the nervous centres in six cases: in three they were perfectly healthy; in three they presented slight microscopical changes which were believed to be merely senile. In some cases recorded by other observers there has been an obvious atrophy of the brain, but not more than is often found in persons of the same age. Eulenburg, in his paper in 'Ziemssen's Handbuch,' places paralysis agitans among "neuroses."

It is by no means a common complaint. During the ten years from 1866 to 1875 only fourteen cases were admitted into the wards of Guy's Hospital, from 1876 to 1885 eighteen, and from 1886 to 1889, eight.

Age.—Parkinson speaks of paralysis agitans as seldom occurring in persons below the age of fifty; but among the forty cases at Guy's Hospital there were twenty-one in whom it began at an earlier age, and in nine of them before forty. Of these nine, four were thirty-six, one thirty-two, three thirty-eight, and the youngest was but twenty-one years old. This last instance is not without precedent; for Charcot mentions a case of Duchenne's in which the patient was only twenty, and one of Fioupe's which occurred in a girl of fifteen or sixteen who had been terrified by a bombshell during the siege of Paris. In thirteen of our forty cases the disease began between the fiftieth year and the fifty-ninth, and there were six in which the patient was still older when first attacked, the age varying from sixty-one to seventy-three.

Sex.—Charcot says that paralysis agitans is equally common in women and in men; but in all Parkinson's cases, and in twenty-nine out of our forty cases, the patients were of the male sex.

Origin.—The disease seems frequently to arise without any definite exciting cause; but sometimes it follows close upon some violent shock of terror or other emotion. Charcot says that in many of his female patients it developed itself during the political commotions so frequent in France. The prolonged action of cold and moisture has been mentioned as occasionally giving rise to paralysis agitans, but apparently on no satisfactory grounds. It has sometimes followed a local injury, as in a case of Charcot's, that of a lady who severely bruised her left thigh in falling from a carriage, and in whom shortly afterwards that leg began to shake, and at a later period all the other limbs.

Diagnosis.—The recognition of paralysis agitans is seldom difficult. A disease which was until recently confounded with it is the insular or multiple sclerosis described in a previous chapter; but the points of distinction between them are clear (cf. p. 545).

In the tremors of age the head shakes when the patient is sitting at rest, and the hands when he moves them. But it is doubtful whether a strict line of separation can be drawn between paralysis agitans and the tremor which is so common in old people, and which (as Dr Maclachlan found among the inmates of Chelsea Hospital) has little or no tendency to shorten their lives. He mentions one case in a pensioner, aged 107, who had been affected with it ever since he was sixty. But it may be that the same affection, which in young subjects is progressive, is in older persons comparatively stationary, or runs so slow a course that death over-

takes them before it has had time to develop itself fully. Dr Handfield-Jones has, indeed, expressed an exactly opposite view, namely, that shaking palsy in young subjects is a less serious form of the disease and curable, whereas in older patients it is incurable; but there seems to be no adequate evidence in support of this opinion.

One must not forget that local organic disease of the brain—a tumour, for example—may give rise to paroxysmal attacks of spasm in one arm, or in one arm and leg, which are not unlike those of the commencement of paralysis agitans; but the history of the case and the other symptoms will generally prevent one from making a mistake in this direction.

Hysteria may simulate this disease. Thus, in a girl of eighteen, the right arm began to shake three weeks after a fright. When she was admitted into the hospital it was in a state of continuous agitation, and if it was held the other limbs began to move in a similar way. However, she had a screaming fit the very day after her complaint began, with globus and headache. She was treated with frictional electricity, and quickly recovered.

Prognosis.—Paralysis agitans is a disease which runs a very slow course. Charcot speaks of it as sometimes lasting thirty years. But even at an advanced period of the disease recovery sometimes takes place. Towards the end the patient sometimes falls into a very sad condition. The movements, which are now incessant, at least while he is awake, may be so violent as to shake the bed in which he lies. He is unable to get up or to dress or feed himself without assistance. His speech may become unintelligible. His mouth remains open, and the saliva runs from it. His fæces and urine are passed involuntarily. Bedsores may form, and he may die of sheer exhaustion, or he may be carried off at an earlier period by pneumonia or some other intercurrent disease. Charcot remarks that a few hours before death the movements sometimes cease entirely.

Treatment.—Dr Elliotson supposed that he cured one case with the subcarbonate of iron; Brown-Séquard that he cured another with chloride of barium. In three of our cases the last-named salt was given in doses of gr. ¼ to gr. j. In two it seemed useless; in the other marked improvement took place, the patient (who was under Dr Moxon's care) being able within six weeks to walk twice the length of the ward merely holding a nurse's hand, whereas he had been so helpless as to be unable to get in or out of bed, and for five years he was dressed by others. A man, after taking two grains of valerianate of zinc three times a day, went out of the hospital "cured," but the noise of a passing waggon, as he was walking home to Bermondsey, brought back the jerking movements, which had ceased entirely for several days. Dr Ramskill (Syd. Soc.'s translation of 'Trousseau,' vol. i, p. 499) had a well-marked case in which recovery occurred, after the failure of other treatment, under the administration of four minims of phosphorised oil of the Prussian pharmacopœia in a drachm of cod-liver oil three times a day.

A plan recommended by Eulenburg consists in the subcutaneous injection of liquor potassæ arsenitis diluted with two parts of water. The quantities which he employed would correspond with from 1½ to 2½ minims of Fowler's solution. But Charcot has made trial of this treatment, and found it useless. Dr Shaw, the medical registrar at Guy's Hospital, in a report made for the second edition of the present work, states that nitroglycerine and physostigma have been tried without effect.

Eulenburg says that he has employed galvanism without any benefit—the constant current passed through the head or along the sympathetic nerves. We have had at Guy's Hospital one or two cases (among more failures) in which the application of this form of electricity down the spine caused temporary improvement. The most striking was in a patient of Dr Habershon's. It was first found that galvanisation for ten minutes was attended with marked benefit for the time. The electrodes were therefore fixed upon the neck for three hours without intermission. After this treatment had been continued for some time the limbs became much steadier, but he was not cured. Dr Wilks used to say that no medicines do any good, but that galvanism sometimes relieves.

At an early stage, when one limb only is affected, it might be worth while to try the effect of keeping it at absolute rest for a period of several weeks, if necessary by the aid of a mechanical appliance.

TETANUS.*—We now come to a dangerous and happily rare neurosis accompanied with most severe tonic spasms. Its history dates back to classical times; and so completely has the word become identified with *tonic spasm*, that it is applied by physiologists to any continuous contraction of a muscle. There are, however, several distinct neuroses which are all attended with continuous spasms—Tonic Wryneck, Tetanilla, Trismus neonatorum, and Hysterical Contractions of the Limbs. Evidently, therefore, something more than the presence of tonic muscular spasms is required to characterise tetanus. Further definition is found in the *distribution* of the spasms, in their more or less constant *order of development*, in the traumatic *origin* of the disease, and above all in its rapid *course* and fatal *issue*.

Symptoms.—In the great majority of cases tetanus begins with stiffness or rigidity of certain muscles of the face or neck. Very commonly those first affected are the masseters and the other muscles of mastication; the consequent inability to open the mouth is known as *trismus*, and has given to tetanus the English name of "lockjaw." Sometimes the earliest symptom is a "stiff neck;" or it may be a peculiar grinning expression of the face, as in a little girl who some years ago died in Guy's Hospital: her mother found fault with her for making faces; but soon afterwards the poor child was nearly choked by spasms in attempting to swallow food. The disease is often first discovered when the patient wakes up in the morning. As a rule it is preceded by a wound, or by an injury of some sort, sometimes not sufficiently severe to require surgical treatment. Occasionally before the tetanus sets in darting pains are complained of in the injured part, which may shoot up the limb; there are four instances of this among seventy-two cases which were collected from our books for the 'Guy's Hospital Reports' in 1857 by the late Mr Poland. Some cases are said to have been ushered in by rigors, but, as a rule, there are no premonitory symptoms whatever.

Possibly the trismus and other early symptoms, after lasting a few days, may (it is said) subside, and the disease aborts; but far more frequently the tonic spasm increases and spreads to the muscles of the trunk and limbs. The face acquires an unnaturally aged appearance, the forehead is wrinkled, and the features drawn. The angles of the mouth are wide apart, and the lips are stretched over the closed teeth, so as to produce a fixed smile,

* Τίτανος (a stretching, strain, tension, from τείνω), used by Hippocrates and late classical writers—Rigor nervorum (Celsus)—Lockjaw.—*Fr.* Tétanos.—*Germ.* Starrkrampf.

which is known as the *risus sardonicus.** The naso-labial furrows are exaggerated. The eyelids are half closed; their muscles are seldom affected by the cramp. The jaws are sometimes clenched so firmly that not even a paper-knife can be wedged in between the teeth. The trunk is rigid, and it is almost always curved, so that the back forms a deep hollow. Thus the occiput is buried in the pillow, and the throat is stretched upwards. If the patient were to attempt to lie straight his body would be supported upon the head and the heels. This condition is called *opisthotonos.* The chest is thrown forwards, and is more or less fixed in a state of expiration, while the abdomen is flat or hollow. The tension of the affected muscles is obvious to the touch and sight; this is particularly the case with the recti abdominis, which feel "as hard as boards," and stand out in knotty masses. Sometimes their fibres give way, and blood is extravasated so as to form a palpable swelling. The limbs are commonly extended, and there may be a marked stiffness of the shoulders and hips, and less often of the elbows and knees. Beyond a little undue resistance to passive flexion of the wrists, there is seldom any impairment of the movements of the hands or fingers. In one case it was recorded that the soles of the feet were arched and the extensor tendons rigid.

From an early period of the disease there is *pain* resembling that which is experienced in a limb affected with cramp, and one of the first symptoms is often an acute pain at the lower part of the sternum piercing through to the back; this is supposed to be due to spasm of the diaphragm. There may also be a distressing sense of oppression from embarrassment of the breathing, and the same cause may reduce the voice to a whisper. The patient is frequently unable to micturate in consequence of the rigidity of his abdominal muscles.

According to Rose, of Zürich, many cases of tetanus end fatally without being attended by any symptoms beyond those which have been already described, but as a rule the spasms undergo aggravation from time to time at longer or shorter intervals; during these paroxysms, which last from a few seconds to three or four minutes, the aspect of the patient becomes frightful. The contraction of the features and the opisthotonos are greatly augmented. The tongue is often caught between the teeth and severely bitten. The face and even the hands become livid from interference with the respiration. These paroxysms sometimes seem to arise spontaneously; sometimes they are obviously reflex, being brought on by a touch, a draught of cold air, a sudden noise, or some voluntary effort, such as the attempt to turn round, to speak, or to swallow. They are generally attended with great increase in the pain, often by extreme anguish. Sir Gilbert Blane, however, met with a case in which, although it terminated fatally, there was merely a tingling sensation of rather a pleasurable kind.

Sleep is generally impossible from an early period, but Watson relates how, when a patient fell asleep, the spasms ceased for the time; even the abdominal muscles became perfectly soft and yielding, but instantly resumed their contracted state as soon as he awoke. The mind is clear and unclouded; only when the end is near at hand is there sometimes slight delirium.

* *I. e.* as usually interpreted, the Sardinian laugh: from the classical tradition of an herb growing in Sardinia (Σαρδώ) which produced involuntary facial spasms. Cicero has *ridere γέλωτα σαρδάνιον*; and this form, used by all Greek writers from Homer to Plato and afterwards, makes the above derivation doubtful.

The pulse is at first natural, but towards the last it becomes very rapid, perhaps 160 or 200 in the minute.

It was long a disputed question whether tetanus is attended with fever. Recent observations have shown that the temperature may be normal throughout the whole course of even the most acute and severe cases; while in those which are comparatively slow in their progress the thermometer occasionally indicates 102° or 103°. Before death hyperpyrexia sometimes rapidly develops itself, temperatures of 110° or 112° being registered. The suggestion has been made that the heat evolved is due to the tonic muscular contractions. But only a small part of the rise can be accounted for in this way, and its great height must be ascribed to disturbance of a central regulating machinery, exactly as when the same thing occurs in a case of fractured spine, of cerebral hæmorrhage, or of the *status epilepticus*. Tetanus is among the few diseases in which the temperature has been observed to rise one or two degrees after death.*

The skin is often bathed in sweat, and an eruption of sudamina is not infrequently present. Dr Wilks has recorded in the 'Guy's Hospital Reports' for 1872 an instance in which the perspiration from the forehead gave to white linen a reddish stain, which, however, Dr Stevenson found not to be due to the presence of blood.

Varieties.—The symptoms of tetanus sometimes deviate from the ordinary type. In ancient times several species were distinguished. Thus it was said that the body may be arched forwards instead of backwards, so that the head and the knees meet in front of the chest; and this was called *emprosthotonos.*† In another variety, for which the name *pleurothotonus* has been invented, the curve is on one side. But it has long been known that, in comparison with opisthotonos, both are exceedingly infrequent, and it is absurd to make of them separate kinds of tetanus. Indeed, Rose has lately maintained that they are really never seen in this disease, although they may occur in hysteria.‡

In 1870, however, a woman, aged forty, died in Guy's Hospital of tetanus, in whom it is said that "the anterior muscles were mainly affected, so that there was a condition of emprosthotonos."

There is one aberrant variety, in which the earliest symptom is muscular spasm of the part originally injured, and in which the paroxysms, when they set in, affect those muscles far more than others. Such a case was recorded by the late Mr Key in the third volume of the 'Guy's Hospital Reports,' and we have since had a well-marked instance of the same kind.

An occasional complication of tetanus, to which Rose has drawn attention, is facial paralysis. In 1871 a woman died under Mr Poland in Guy's

* This heat has then been supposed to be derived from the stiffening of the muscles in *rigor mortis*. This explanation, however, does not seem to be quite satisfactory, for although the *post-mortem* rigidity is said to begin early, and also to last longer than usual, there appears to be an interval of relaxation from the vital spasm before it sets in.

† "Neque tamen alius importunior acutiorque morbus est quam is, qui quodam rigore nervorum, modo caput scapulis, modo mentum pectori annectit, modo rectam et immobilem cervicem intendit. Priorem Græci *ὀπισθότονον*, insequentem *ἐμπροσθότονον*, ultimum *τέτανον* appellant: quamvis minus subtiliter quidam indiscretis his nominibus utuntur" ('Celsus,' lib. iv, cap. iii; also 'Cælius Aurelianus de Acut. Morb.,' lib. iii, cap. vi).

‡ The French military surgeon, Larrey, has been the great authority for the occurrence of emprosthotonos in tetanus; but Rose shows by detailed criticism that none of his cases belonged to any but a very mild form of tetanus. Moreover, this position of the body is, after all, frequent in patients suffering under irritation of the nervous centres. Larrey entertained the notion, certainly without foundation, that the distribution of the spasms varied according as the wound which caused the tetanus was in front or behind.

Hospital, in whom this symptom was present on the left side, and whose ocular muscles were also affected in a strange way, the left eye being immoveable, turned upwards and outwards, while the right one was as rigidly set straight forwards. Neither meningitis nor any lesion of the brain was discovered at the autopsy. The original accident was a fracture of the orbital plate of the frontal bone, caused by the point of an umbrella. This corresponds with a statement of Rose's, that the starting-point of the tetanus in such cases is always within the distribution of the facial nerve; he supposes that the trunk of the nerve becomes swollen, and is compressed within the bony canal through which it has to pass. If this view is correct, the symptom in question affords a proof of the occurrence of an "ascending neuritis" in tetanus, and is thus of great theoretical interest. Indeed, in some few cases nerve-trunks are said to have been found reddened and swollen in parts of their course; but as such changes are often not to be discovered, it is doubtful whether they are of much importance.

Ætiology.—In reference to the *causes* of the disease there are various questions, which are fully discussed in surgical works, as to how far the extent or the seat of an injury depends on the healthy or unhealthy state of the lacerated structures, or on injury to a nerve, or the introduction of foreign bodies.* But it is important for the physician to be alive to the fact that tetanus often follows very slight cuts and trifling abrasions, which are apt to be forgotten by the patient. Rose says that nearly half of his cases were sent into the hospital as cases of "rheumatism" or of some internal disease. Instances have been recorded in which tetanus has apparently been set up by the extraction of a tooth, by venesection, by the application of a blister or a cupping-glass or a seton, by the sting of a bee, and by a cut from a whip. It has now and then been observed after simple fractures of the limbs, or after blows or falls upon the back of the neck, without any breach of surface. In 1860 a girl, aged five, died in Guy's Hospital, who on the day before she was attacked by the disease had a fall in which she slightly strained her back and grazed her elbow. Three other patients showed, one a slight scar over the knee, another a small sore on the elbow, and the third a little scab with pus beneath it at the elbow, in addition to a cicatrix half an inch long on the forearm, due to a cut received about six weeks previously. In 1873 a boy was admitted under the author's care in whom stiffness of the neck and jaws had come on four or five days after the healing of a small "gathering" on one great toe, due to irritation from a nail in his shoe. This patient recovered. Again, tetanus has sometimes occurred soon after parturition or abortion. In a case which was observed at Guy's in 1870 no cause could be discovered but a prolapsed and excoriated cervix uteri.

There is a special ætiological variety of the disease—*tetanus neonatorum*—which affects infants, usually in the end of the first or during the second week after birth. It is believed to be the result of an ulcer of the navel.

In two of our cases, in which the disease appeared to be referable to a trifling injury, it is possible that *cold* helped in its production. One was a patient of the author's who, besides having a festering sore on the elbow, had got wet through in a shower of rain three days before the tetanus set in; this perhaps affected him the more because his work was behind the ovens at a biscuit manufactory. The other was a man under Mr Bryant, who had a slight scratch on the little finger, which soon healed;

* See M. Bowlby's remarks on this subject (*loc. cit.*, p. 304).

he also was exposed to wet two days before being attacked with stiffness of the shoulders.

It seems to be an established fact that in some cases in which tetanus is clearly traceable to a severe wound it is, nevertheless, also due, in part, to changes of temperature. Army surgeons have often noted that after a battle the wounded are especially apt to be attacked when they lie in tents on a damp surface, or when cold nights follow hot days.

The liability to exposure to draughts in tropical climates may be one reason of the frequency with which, as is well known, the disease follows all sorts of injuries among the coloured populations of the East and West Indies; and the same seems to have been true in ancient Greece and Italy, where tetanus was well known. It is among the diseases which Hippocrates ascribes to cold (Aphor., v, 17).*

Moreover, there appears to be no doubt that cold sometimes gives rise to tetanus directly, in persons who have received no injury whatever. On July 17th, 1863, a man sat in a draught, and afterwards felt a stiffness in his limbs; this continued during the 18th and the 19th; on the 20th more marked tetanic symptoms set in, and he came to Guy's Hospital and was admitted; at 7 a.m. on the 21st he had a severe paroxysm affecting his chest, in which he died. Another patient, in 1869, had got his feet wet the day before the disease began. Sir Thomas Watson cites a case from Dr Gregory of a man who, "having fallen asleep in moist grass, awoke with a stiff neck, which afterwards went on into regular tetanus."

But it now and then happens that not even this cause can with any plausibility be assigned, so that the occurrence of tetanus remains altogether inexplicable in the present state of our knowledge. Three such cases have ended fatally in our wards between 1863 and 1875.

Whenever the disease arises independently of an injury—whether or not after exposure to cold or wet—it is called "idiopathic," to distinguish it from ordinary "traumatic" tetanus.

On the whole, tetanus is more common in men than in women, in young persons than in those who have passed the middle period of life, and in the robust and the healthy than in those who are weakly or diseased.

Pathology.—Formerly pathologists were agreed that there are no obvious changes in the nervous centres in cases of tetanus. But in 1865 Mr Lockhart Clarke recorded in the 'Med.-Chir. Transactions' (p. 255, pl. iv) some cases in which he believed that he had discovered areas of semi-fluid disintegration, or white softening, in the grey matter, but also in the white columns of the cord. Similar observations were afterwards made by Benedickt and by Dr Dickinson, who considered that the leucocytes found in the peri-arterial sheaths of the same structures denoted an inflammatory exudation. Still more recently Dr Coats, of Glasgow, has demonstrated like appearances in the bulb and the pons. These pathologists also lay stress on the congested state of the blood-vessels, but that had long ago been shown to have no real significance, being attributable either to the mode of death by dyspnœa or to gravitation after death. Whether greater importance is to be attached to the supposed lesions above referred to is still doubtful, and the doubt applies to other diseases beside tetanus.

In his article on Tetanus in 'Holmes's System of Surgery,' the late Mr

* "Frigus modo nervorum distentionem, modo rigorem infert: illud σπασμός, hoc τέτανος Græce nominatur" ('Celsus,' ii, 1). The context shows that this statement is directly taken from Hippocrates.

Poland argued against a primary central lesion (or an ascending peripheral neuritis, as it would now be called—*a neuritis migrans*, as Lockhart Clarke supposed), and in favour of the view that tetanus is really a "specific" disease, a form of blood-poisoning. This hypothesis has lately been supported by Professor Coats, by Mr Bowlby, and by many pathologists abroad. Experiments to ascertain whether it is transferable by inoculation, and to isolate the contagion of bacteria if present, have been undertaken by Rosenbach, Rietsch, Abadie, Brieger, and others. See a review of this part of the subject by Mr Wm. Anderson, of St Thomas's Hospital ('Lancet,' Feb. 4th, 1888). In Eichhorst's 'Handbuch' tetanus is no longer found with other affections of the nervous system, but with infective diseases.

Diagnosis.—This is seldom difficult. It is only at the very commencement of *trismus* from dental irritation in infants that one could mistake it for true "lockjaw." Rose says that even at the earliest period of tetanus he has always been able to discover a certain degree of stiffness of the back of the neck, the patient being unable to bring the chin freely down to touch the chest. Another practical suggestion of his is that by introducing one's finger into the patient's buccal cavity on each side one can feel the hard edge of a rigid masseter much more distinctly than from outside the cheek. Inability to open the jaws, from any chronic affection of the temporo-maxillary joints, is in this way easily distinguished from all forms of trismus.

Tetanus is sometimes simulated by *hysteria*. Sir Thomas Watson mentions an instance of this kind in a girl, who "would all at once be drawn into a position such that the top of her head and her feet alone supported her, while her body was bent backwards like a bow; then, after a time, with equal suddenness, the opposite position was assumed, her forehead and her knees being brought together." His statement suggests the criterion which is applicable to all cases of this kind; namely, the irregular and inconsistent nature of the symptoms. Another affection which has perhaps to be considered is *spinal meningitis*. A case given in 'Reynolds' System' as a typical example of the latter disease would show that it may very closely resemble tetanus; but, as Moxon argued, that may, after all, have been tetanus.

The most important point of diagnosis is between tetanus and the effects of *strychnia*. A boy, aged twelve, was brought into Guy's Hospital at nine o'clock one morning, suffering from opisthotonos, and from spasms of the respiratory muscles, so severe that he almost ceased to breathe. He was a druggist's boy, and confessed that between 7.40 and 8.30 a.m. he picked up some black stuff (afterwards ascertained to be extract of nux vomica) and put it into his mouth for liquorice, until he found it bitter, and spat out as much as he could. Ice applied to his spine gave him relief. From some urine passed at 1.20 p.m. Dr Stevenson succeeded in obtaining the colour reactions of strychnia and brucia. By that time his symptoms had passed off, and he was discharged from the hospital a few days later. The characteristic features of such cases are the suddenness with which opisthotonos and the most violent general spasms set in, the absence of persistent rigidity of the affected muscles during the intervals (so that the mouth can be freely opened), the fact that the hands are involved, and the rapid death or recovery which ensues. Even if the poison be administered in small doses, and repeated at frequent intervals, there is no reason to suppose that strychnia could simulate the progressive development of tetanus.

Fatal event.—As a rule tetanus ends fatally between the third and the

seventh days. The occurrence of death within twenty-four hours from the commencement of the disease is very infrequent. Among Mr Poland's seventy-two cases there were only two instances of it: one patient, a young man, who was attacked six days after admission with a compound fracture of the leg, died in nineteen hours; the other, a girl, who had been burnt, is said to have lived only four or five hours. The most quickly fatal case on record is one of a negro servant, who lacerated his thumb in breaking a china dish, and who was almost instantly seized with convulsions, and died in a quarter of an hour; but Sir Thomas Watson, although he cites it, expresses a doubt as to whether this was a genuine example of tetanus. In most instances death occurs during a paroxysm, and is believed to be often due to spasm of the diaphragm or of the glottis. Mr Poland mentions that in one of his cases the heart's action continued for a short time after the breathing had ceased. In 1875 a patient suffering from tetanus in Guy's Hospital on several occasions turned perfectly livid, so that he seemed to be at the point of death, although a clenched state of his hands was the only outward indication of an increase of spasm. At last, after four days, one of these seizures did in fact prove fatal. Bauer, in Ziemssen's 'Handbuch,' however, expresses the opinion that the danger from failure of the respiration in tetanus has been generally over-estimated, for carbonic acid poisoning, he says, relaxes the muscles before death can take place.

There is no doubt that the immediate cause of death is sometimes sudden failure of the heart. Rose relates an instance in which he had his finger on the pulse when it suddenly stopped for ever; but here there was also hyperpyrexia present. Some observers have supposed that in cases of this kind the ventricles are seized with spasm. Stress has been laid on the fact that after death the heart is often found closely contracted, but this is in all probability the result of rigor mortis. Rose argues that the real cause of death is cardiac paralysis; he thinks that the muscular contractions oppose a resistance to the circulation through the arteries which the heart is unable to overcome.

Lastly, there are cases in which life is prolonged for three or four weeks, but which yet ultimately prove fatal. The cause of death is then generally exhaustion. Sometimes the spasms have altogether subsided, so that the patient is thought to be in a fair way towards recovery, although he is excessively weak and emaciated and prostrate, with sunken features and a scarcely perceptible pulse. Among the cases collected by Mr Poland there are two which proved fatal during a paroxysm as late as the twenty-first or the twenty-second day, and two others in which death was referred to exhaustion on the sixteenth and the thirty-second days respectively.

Convalescence.—When recovery from tetanus takes place a certain degree of stiffness of the muscles often remains for a considerable time, and very slowly passes off. Mr Poland mentions a case in which there was still some stiffness of the jaws after a year had elapsed. In 1871 Mr Golding-Bird had a boy under his care in Guy's Hospital in whom the spasms lasted for fifty-one days, and even after they had subsided his limbs still remained rigidly flexed, he became exceedingly emaciated, and bedsores developed, so that, although he was floated on a bath on water, he ultimately died on the one hundred and seventh day.

Course.—Although almost all writers recognise an acute and a chronic form of tetanus, they generally admit that no line of demarcation can be drawn. It is true that when successive cases are arranged in groups according

to the length of time which happened to elapse between the injury and the onset of trismus or of stiffness of the neck, a rapidly fatal termination is found to occur more frequently in those in which the trismus is early than in those in which it is late. A similar difference in intensity, although not so marked, seems to be observable in cases in which the primary lesion is extensive and severe, as compared with those in which it is slight. It is therefore not surprising that instances of "idiopathic" tetanus should, as a rule, be less urgent in their symptoms than those which are of "traumatic" origin; and since the subsidence of the disease, in those cases which recover, is never otherwise than gradual, one can understand how it has come to pass that the idea of chronic tetanus has become associated not only with a hopeful prognosis, but also with the absence of a severe injury, or of any injury at all; or, again, with the occurrence of a long interval since the date of an injury, rendering the connection between them doubtful. But although this is tolerably correct, so far as groups of cases are concerned, it is very apt to mislead when applied to an individual patient. In some instances of idiopathic tetanus death ensues as rapidly as in most of those which follow quickly upon a severe compound fracture or a burn. The division into acute and chronic tetanus had better be given up altogether.

Prognosis.—The only ground on which a forecast of the disease can with any safety be based is that afforded by the rate at which the symptoms of the disease are developing in the particular case under observation. Unfortunately it must be added that rapid progress is much more surely indicative of a fatal ending than is a slow course of a good prospect of recovery, or even of certainty that death is very near at hand. Spasm of the respiratory muscles sometimes destroys life suddenly and almost without warning. The average mortality of the disease among the seventy-two cases collected by Mr Poland in 1857 was 86 per cent.*

Treatment.—The difficulty of prognosis in tetanus leads to a corresponding difficulty in estimating the results of treatment. There are, indeed, certain measures the propriety of which is obvious. The patient should be placed in a quiet, dark room, and should be withdrawn from all noise and bustle, and from the visits of too many friends. He should speak as little as possible. The food which is given to him should be nutritious but in a fluid form, with wine or brandy in full quantities. If he is unable to swallow, enemata of beef-tea and brandy may be administered at regular intervals, unless even this brings on paroxysms of spasm, as is too often the case. Rose makes the practical suggestion that anæsthesia should be induced regularly once or twice a day by chloroform, for the purpose of injecting food into the stomach through a tube. Purgatives should not be given after the commencement.

Probably amputation of an injured limb or division of a nerve leading

* Some years ago Dr Wilks and the author saw with Dr Anderson, of New Cross, a gentleman whose symptoms seemed to deviate from the ordinary features of tetanus. It was one of those instances in which the paroxysms constitute the most marked element of the disease, but in which, although they recur but seldom, they destroy life early. The patient's main complaint was of a spasmodic pain in the right hypochondrium, which he attributed to wind. When it came on he used to get up and walk about, declaring that he could not lie down; he would stand leaning against the bedpost, and would call to his wife to rub his back. About a fortnight previously he had run a garden fork through his great toe; four days before we saw him he began to complain of stiffness of his jaws, and from that time he was unable to open his mouth fully. These facts led to a strong suspicion that the abdominal pain was due to tetanic spasm. He died three days after our first visit, and about twenty-four hours after sitting up in bed to make his will.—C. H. F.

from a wound are of no avail. But it must be remembered that a splinter of wood or some other foreign body has been now and then unexpectedly found under a cicatrix, or embedded in a nerve-trunk.

As regards the treatment of tetanus by drugs, we know of no medicine sufficiently potent to arrest the course of this terrible malady. When it runs a rapid course, one can often do nothing better than keep the patient continuously under chloroform, so as at least to secure euthanasia.

On the other hand, when the progress of tetanus is slow, it often seems that the death of the patient is little more than an accident, from the supervention of a paroxysm which happens to exceed a certain limit of severity. In such cases one might hope that narcotic medicines, or those which relax the muscles, would save life. With this object, as well as to relieve the patient's sufferings, *opium* has been often employed. Sir Thomas Watson mentions the case of a lady who took more than four ounces of laudanum a day during twenty days, and who recovered. And he refers to another case in which an ounce of solid opium was swallowed in divided doses every day for three weeks. Of late years the hydrate of *chloral* has sometimes been used in cases of the same kind with apparent success. In 1870, for instance, Mr Birkett had under his care at Guy's Hospital a man, aged twenty, who on June 24th had received a kick on an ulcer. Next day he felt rigidity of the muscles of the face and was unable to swallow solids. He was admitted on the 28th. At first thirty grains of chloral were given every four hours, but on the 30th, thirteen doses having been taken, a grain of opium was ordered to be taken every three hours instead. However, the spasms became more severe; and on July 4th a drachm of chloral was prescribed at one dose, and half a drachm on the following evening. After this fifteen grains were given every other hour until the 11th, when the quantity was increased to twenty-five grains every other hour. Two days later it was reduced again, and the disease now gradually subsided in the course of the next three or four weeks. A full report of this case will be found in a paper in the 'Guy's Hospital Reports' for 1878 by Dr Frederick Taylor, who remarks that in some other instances chloral has been found to give rise to great drowsiness, without much affecting the spasms.

Among the depressants of muscular action *physostigma* has been employed at Guy's Hospital in one case which ended favourably. The patient was a man aged twenty-one, who, having got drunk on November 30th, 1874, began to suffer from stiffness in the back on December 1st. He was admitted, under Dr Wilks, with fully-developed tetanus, on December 5th, and spasms recurred every three or four minutes. The extract of Calabar bean was given at first in small doses, but afterwards one grain every two hours; and on the 10th, after a very severe seizure, seven doses of a grain each were administered at intervals of fifteen minutes in succession. He began to improve about December 17th, but the stiffness of the joints remained until after the middle of January, 1875. Against this case must be set another one under the author's care in the summer of 1875, in which death occurred on the sixteenth day, in spite of two and a half grain doses of extract of physostigma repeated at intervals of only an hour. Previous to these two cases was one published in the 'Practitioner' in 1874 (vol. xiii, p. 345), in which enormous doses of physostigma were followed by recovery.

Subcutaneous injections of *curare* were administered to a man under the care of Mr Durham in 1876; but it seems doubtful whether the doses

which were employed were sufficiently large to be really efficacious, although the report says that they were followed by sleep and relief of pain.

Another medicine which has now and then been used in cases that ended in recovery is quinine. An instance of this was recorded by Dr Bright in the first volume of the 'Guy's Hospital Reports.'

In the collection of cases published by Dr Taylor in the same 'Reports' for 1878, there are recorded nine in which death occurred under chloral (six by the fourth day, and the other three on the eighth, tenth, and twelfth days), and seven which ended fatally under Calabar bean (six by the fourth day, the seventh on the eighth day).

CHOREA.*—The term St. Vitus's dance—*chorea Sancti Viti*—was originally applied to the dancing mania which prevailed in certain parts of Germany in the fourteenth and fifteenth centuries. It was also known as St John's dance. It is said that the designation is first met with in the account of an epidemic at Strasburg in 1418, when those who were attacked were sent to the chapel of St Vitus, at Zabern, to be calmed by religious processions and masses. Such cases will be hereafter mentioned under hysteria, and are related to some forms of saltatory spasm (p. 701).

The disease now to be described was named chorea first by Sydenham,† and for a long time afterwards Sydenham's chorea was distinguished as "chorea minor," or "chorea Anglorum."

Symptoms.—These are chiefly two: inability to keep at rest while awake, and incapacity to perform voluntary movements with precision. If the patient means to sit or to stand still, she (for chorea is more common in girls than in boys) begins after a few seconds to fidget. She shuffles her feet over the floor, or throws one foot over the other, or twists it first outwards and then inwards. Or, perhaps, she lays her hand palm upwards upon her lap, and then suddenly reverses it. Or she may shrug up one shoulder, or throw it forwards, or open and close her mouth or her eyelids without purpose. The muscles of the face are continually working. She probably is herself unaware of some of the movements, as, for instance, when a squint develops itself, or when her eyeballs are jerked from side to side. If one asks her to show her tongue she often seems at first unable to put it out, but afterwards she suddenly thrusts it forwards, and then as suddenly withdraws it, her jaws snapping together in front of it. If she wishes to carry a cup to her mouth she cannot help throwing her arm in various directions, and accomplishes her object only after several unsuccessful attempts, and then she perhaps seizes the edge of the vessel with her teeth, and is obliged to gulp down all its contents at once for fear of spilling them. When she tries to walk she moves by fits and starts, and jerks her body and limbs first to one side and then to

* *Synonyms.*—Chorea Sancti Viti minor—Chorea minor—Chorea Anglorum.—*Fr.* Danse de Saint Gui.—*Germ.* Vitustanz.

† "De Chorea Sancti Viti: Convulsionis species quædam est, pueros puellasve a decimo ætatis anno ad pubertatem invadit, &c. . . . . Antequam poculum ad os possit addacere, mille gesticulationes, circulatorum instar (like a mountebank), exhibebit. Non enim rectâ lineâ ori admovet, sed deductâ a spasmo manu, huc illuc aliquandiu versat, donec tandem forte fortunâ labris proprius apponens liquorem, repente in os injicit et avide haurit" (Sydenham: 'Processus integri in morbis curandis,' 1693). It is remarkable, that while Romberg calls Sydenham's original description of chorea masterly, and von Ziemssen says that it leaves nothing to be desired for clearness and precision, Dr Sturges thinks we must suppose either that the period and manner of its attack have changed since Sydenham's time, or else that this observer was in gross error in his description of what he saw.

another. Attempts at voluntary movement bring on the choreic symptoms worse, whereas in slight cases a child may lie quiet in bed or sit still, without anything seeming to be wrong until she is spoken to.

The respiration is disorderly in rhythm. The articulation is apt to be hurried. The patient, if told to count, may count several numbers one after another with explosive violence, and then pause to take a deep breath; or she utters only one sound with each expiration, drawing in air hastily before she goes on to the next. Von Ziemssen says that he has seen with the laryngoscope unsteady and quivering movements of the muscles of the glottis, and that an imperfect degree of tension of the vocal cords is shown by the low pitch and monotonous character of the voice, and by the short time that a note can be kept up in singing. Romberg relates a case in which there was annoying hiccough, and two others in which inspiration was attended with a whistling noise; in one of them the chest was observed to be suddenly drawn inwards by spasm of the intercostal muscles. According to Trousseau deglutition is sometimes impaired.

During sleep the choreic movements cease. Jaccoud also remarks that in slight cases they sometimes remain absent for a while after the patient awakes. Marshall Hall, however, is said to have observed that if she dreams they may for the time return during her sleep.

Rosenthal and Benedikt have tested the reaction of the muscles to faradic and galvanic currents, and have found their excitability greater than under normal conditions. There is no reaction of degeneration.

When chorea is slight or of moderate severity the spasms are often confined to one side, so far as the limbs are concerned. This has been called "*hemichorea*," but a special name is hardly needed. Dr Hughlings Jackson has pointed out that, even in these cases, the muscles of the trunk and face are always affected bilaterally, a fact of much theoretical interest. Different statements have been made as to the relative frequency with which the right and the left limbs are affected. According to Reynolds and Jackson the former more commonly exhibit the movements; according to Austin Flint, Trousseau, and Jaccoud, the latter. Dr Anstie also remarks that one may often at the first glance recognise a child affected with slight chorea from her sitting with her right hand grasping her left wrist to keep it still. Among thirty-three cases out of 150 in which the affection was unilateral, there were eighteen on the left to fifteen on the right side ('Guy's Hosp. Reports,' 1873, "Rheumatism and Allied Disorders"). Since then, among 164 additional cases, the writer found choreic movement decidedly predominant in the right arm or leg, or both, in seven cases; and in the left in thirteen.

Trousseau states that the patient experiences formication and tingling, or even anæsthesia; but these symptoms are very rarely mentioned in the reports of cases admitted into Guy's Hospital. Choreic patients often complain of headache, and Sir Thomas Watson remarks that he has sometimes known the pain to be limited to the side of the head opposite to the affected limbs. The pupils are generally dilated and torpid, and in one case von Ziemssen observed that the pupil was much larger in the eye corresponding with the affected arm and leg. Rosenthal noticed that the pupils return to their normal condition when the chorea subsides.

Children affected with chorea are generally pale, often decidedly anæmic. They may also be thin and delicate in appearance, but this is often due to

previous rheumatism and cardiac disease; and chorea may be seen in stout and rosy children. We must remember that the favourite age of the disease is not early childhood, but the period between eight and fourteen years of age, when both boys and girls, even when in sound health, are usually slender and often pale if their appearance is compared with the red cheeks and plump limbs of their earlier childhood.

The temperature is normal.* The urine is sometimes scanty and high coloured, in marked contrast with the pale, abundant urine of hysteria. According to Dr Bence Jones there is an excessive secretion of urea, and others have said that the amount of lithates is increased. Analyses made in two cases by Dr Handfield Jones ('Clin. Trans.,' iv) yielded contradictory results.

The pulse is commonly quickened, especially when the movements are severe. Some writers assert that the heart's action may be irregular or intermittent, but this is quite exceptional, even when there has been previous organic disease.

On auscultation a blowing *systolic murmur* is often heard at the apex. With regard to the significance of this sign widely different opinions have been held. Many observers have maintained that the bruit is functional; some that it is anæmic; others that it is due to choreic spasms of the musculi papillares interfering with the due closure of the mitral valve. But when the disease terminates fatally that valve is almost invariably found studded with vegetations like those of rheumatic endocarditis. Since the murmur also is the same in the two diseases it seems reasonable to attribute it to the endocarditis in both. In many cases no bruit is audible. Its absence, however, is not to be taken as a proof that the valve is unaffected, for Kirkes and Wilks have both recorded instances in which vegetations were found after death, but in which the heart-sounds during life had been normal. Again, in some cases in which a murmur is present it passes off as the patient recovers from the chorea. This fact has been regarded as a proof that at least in these cases it is due to functional disturbance, and not to a valvular lesion; but a precisely similar disappearance of the murmur is often observed in cases of rheumatism.

Among 150 cases of chorea in Guy's Hospital during the years 1870–71–72, the state of the heart is not mentioned in eleven, and the presence of any abnormality is expressly denied in eighty. A systolic bruit was heard in the remaining fifty-nine, and in forty-three of them it was distinctly loudest at the apex. In only nine is it described as basic; two of these were indistinct and two were combined with a diastolic murmur.

Among 180 fresh cases in the same hospital during the five years 1874–78, collected for the writer by his house physician Dr George Halstead, sixty-two were reported to have a murmur of some kind (again about a third of the cases); of these it was an apex systolic bruit in fifty-two, a basic bruit in seven (of which two were diagnosed as aortic and two as pulmonary), a præsystolic apex bruit in two, and a pericardial rub in one.

* The temperature cannot be taken in the mouth or the axilla. The rectum, or the stream of urine (p. 37, note), is the proper place for the thermometer. The fact that the constant muscular movements do *not* raise the temperature of the body is of great physiological interest. Dr Woodman and Dr Long Fox (Wunderlich, Syd. Soc. Trans., p. 426) have found it as low as 97° or 96°, although on the other hand is quoted Dr Finlayson's case (probably a complicated one), in which the average evening reading of the thermometer *in recto* was 103·2° (cf. *infra*, p. 744).

In the next ten years (1879–89) Dr Goodall reports a bruit in 143 cases out of 262.

Varieties.—In exceptional cases of chorea the symptoms are but little marked at its commencement, or even throughout its whole course; but there is marked *loss of power* in one or more of the limbs. Thus, the patient may complain that her arm feels heavy, or may drag her foot slightly in walking. Such cases are often brought to one as paralytic. In other instances she merely has a trick of bringing a particular set of muscles unexpectedly into action, so that she makes a grimace, or throws her hand or arm into an odd position. Or she may let a jug fall, and this may happen two or three times in succession in the course of a week or ten days. Or it may be noticed that she does not write her exercises so well as she used, or that she no longer plays steadily on the piano. All these things are apt to be set down to carelessness, and her parents and teachers are the more likely to blame her because she often becomes inattentive and forgetful, apathetic or peevish.

Severe and dangerous cases are happily the exception. They have been separately described as *chorea gravis*. The patient becomes unable to stand; even when recumbent her limbs are tossed about, so that boards well padded have to be fixed on each side of her bed to prevent her throwing herself on the floor. In spite of all the precautions that can be taken, she is very apt to bruise herself and to rub off the skin from her elbows and knees, so as to cover them with crusts and sores. She ceases to sleep altogether, and the violent movements go on day and night without intermission. In such cases emaciation takes place with wonderful rapidity. Dr Tuckwell has related the case of a boy who was wasted to the utmost at the time of his death, but who six days before had borne the appearance of vigorous health, with remarkably well-developed muscles; and conversely von Ziemssen mentions one in which a girl, eleven years old, gained during convalescence 5½ lbs. in ten days, her weight rising from 55½ to 61 lbs. in that time. One cause of the extreme wasting which accompanies severe chorea is doubtless the difficulty with which food is administered. The patient often seizes a spoon, or the spout of a feeding-bottle, as if she would bite it in two, and so injures her own teeth, or her nurse's fingers.

The mental state of a patient affected with severe chorea is often one of mania. She may be continually shouting, singing, and talking at random. Or she may unexpectedly perform some strange action; for instance, a girl who was in hospital some years ago, suddenly got out of her own bed, and turned a somersault across that of another patient. There is no necessary relation between the intensity of the choreic movements and that of the psychical disturbance. Dr Wilks says that the mind remained perfectly clear in one of his patients, who had the worst attack of chorea which he ever saw terminate favourably. On the other hand, there occurred some years ago in Guy's Hospital a fatal case in which there were such marked mania and so complete a loss of consciousness, while at the same time the movements were so like those seen in epilepsy, that the diagnosis remained doubtful until the autopsy was made, when recent vegetations were found upon the mitral valve. Dr Hills, of the Norfolk County Asylum, knew more than one choreic patient who was sent to that institution as insane.

Loss of power of speech is common in all but slight cases of chorea, and is constant in chorea gravis.

Course.—Chorea may be said to be generally a chronic disorder, but its

duration is very variable. Almost all the statistics which have been published concur in stating a period of from two to three months as the average. Thus Wicke found it eighty-nine days in a series of 125 cases, and Sée sixty-nine days in one of 117 cases; while from much smaller data Gray, Tuckwell ('Lancet,' 1871), and Hillier in this country each made it about ten weeks. Individual cases, however, range widely on each side of these limits; but far more widely *beyond* the average duration than *within* it. Hence the introduction of one or two very prolonged cases may greatly disturb the statistical result; patients sometimes apply for treatment in whom the disease has already lasted for many months or even for two or three years. A single instance of this kind would inevitably spoil, for the purposes of comparison, any series which did not embrace a very large number of cases. As a rule, chorea is more likely to last long when its symptoms are comparatively mild; patients who are obliged to have boards placed along the sides of their beds often get well before those who are able to be up and about the ward throughout their stay in the hospital.

Fatal event.—Children very rarely die of chorea. At Guy's Hospital between the years 1848 and 1875, there were only twenty cases of the disease which terminated fatally. And of these five must be left out of consideration, since death was due to an accidental complication, dysentery, diphtheria, rheumatic pericarditis, or cardiac dropsy. Of the remainder there are only four in which the patients were below the age of fourteen; two were seven years old, one twelve, and one thirteen. The remaining eleven patients were more than fourteen years old, nine of them between the ages of fifteen and eighteen, one forty years old, and one fifty years old. Few of the women seem to have been pregnant; but it is an ascertained fact that the mortality is very great in this condition, which frequently ends in abortion or premature delivery. It seldom happens, even in the most severe forms of chorea, that the patient dies within three or four weeks from the commencement of the disease. One of the most rapid cases on record is the one referred to above, in which there was at first a doubt between epilepsy and chorea; the whole duration of the patient's illness was said to be only two or three days. In 1853 a girl aged sixteen, who was already in the hospital for syphilis, was attacked with maniacal chorea, and died in six days. About two months previously, another case, in a boy of the same age, had terminated fatally in nine days. The immediate cause of death seems to be almost always the intensity of the nervous symptoms themselves, but the movements often subside, and may even cease entirely during the last few hours, the patient lying comatose and passing urine and fæces involuntarily. The temperature of the body may rise during this period of the disease. In one case it was 104·7° before the patient died, and Dr Frederick Taylor observed in a case in our clinical ward the thermometer register a temperature of 108° immediately after life was extinct. It does not appear that endocarditis or pericarditis is directly concerned in bringing about the fatal issue. The presence of bronchitis has been noted in several of the reports of autopsies at Guy's; in one instance it perhaps accelerated the patient's death. In 1873 Dr Habershon had a fatal case in a boy aged twelve, who had been three weeks in the hospital when his breathing became obstructed by swelling of the tongue. Tracheotomy was performed, but without saving the patient's life. Probably the glossitis was the result of injuries inflicted by the teeth, for in another instance, in which the tongue had been severely bitten in two places, there was dis-

covered after death a foul ulcer which exposed the sublingual gland and extended for the depth of an inch into the muscular and other tissues.*

Four fatal cases occurred among the 150 tabulated by Mr Manser for the 'Guy's Reports' (Third Series, vol. xix, pp. 329—332). 1. F., thirteen, 5th March. Mitral and aortic vegetations, ulcer from biting tongue. 2. F., seven. Aortic vegetations, faucial diphtheria. 3. F., pregnant; mitral vegetations. 4. M., thirty-eight. Aortic and slight mitral endocarditis.

Among 180 cases collected by Dr Halstead from the records of the same hospital, during the five years following those which furnished the above statistics, there were only five deaths. 5. In a little girl of seven, who died after being six weeks in the ward, there were found the usual fibrinous vegetations on both mitral and aortic valves. 6. In a girl of fifteen, after a month's treatment, there was, beside the same almost constant lesion, lobar pneumonia and a bedsore. 7. In a girl of eight there were mitral and aortic nodules with broncho-pneumonia and adherent pericardium. 8. In a girl of fifteen there was mitral endocarditis, adherent pericardium, and a "cardiac" lung." 9. In a lad of seventeen, who had suffered again and again from chorea since he was nine years old, no lesion but mitral vegetations was found.

If to these nine fatal cases we add the seven additional cases numbered 5—10 in the paper above referred to (vol. xix, p. 333), we have a total of sixteen *post-mortem* examinations. In every one of these there were fibrinous nodules found on the mitral or aortic valves. In only two of these was there a history of rheumatic fever, and in seven its occurrence was explicitly denied. Diphtheria was apparently the cause of death in three cases. In three cases there was acute lobar pneumonia, and in a fourth lobular inflammation of the lungs. Only one of the patients was pregnant.†

Recovery.—This is generally gradual. Sometimes, however, the breaking out of an exanthem, or of some other febrile disease, is followed by the sudden subsidence of the movements. This is in accordance with an aphorism of Hippocrates: *spasmos febris accedens solvit.* Dr Radcliffe states that he has met with seven cases in which it occurred; and some striking examples of a similar kind are recorded by Rilliet and Barthez. According to the observations of Sée, however, the neurosis is not likely to be cut short unless it had reached its acme of development before the commencement of the fever. In many instances the first effect of the latter is to aggravate the movements, and yet in those very cases they may cease when the crisis of the fever has passed.

It sometimes happens that the subsidence of the spasms in severe cases of chorea is not followed by any evident amelioration in the patient's general condition. She may become perfectly quiet, and yet may remain for two or three weeks unable to stand, and with little power in her arms. This paresis may be limited to a single limb, or to the two limbs on one side, the "choreic hemiplegia" of Dr Todd. In association with such symptoms, or independently of them, the intelligence may remain defective; or a condition of mania or melancholia may develop itself. Dr Barnes met

* According to Dr Radcliffe and von Ziemssen meningitis occurs in some cases of chorea, and in others myelitis; and they accordingly mention those affections as sometimes bringing chorea to a fatal termination; but we may venture to doubt the diagnosis of any case in which unmistakable inflammatory changes were not discovered either in the membranes of the brain or in the spinal cord.

† Among 439 cases published by the Collective Investigation Committee only nine deaths occurred ('Brit. Med. Journal,' February 26th, 1887).

with a case in a pregnant woman, who as she regained her strength became insane and had to be removed to Bethlem. Other patients, after the choreic movements have passed off, still remain absolutely silent for days together, making no attempt to reply to the inquiries of their friends. Dr Hughlings Jackson associates such defects of speech with right hemiparesis.

Alarming as these various symptoms are, they almost always pass off in their turn, and the patient ultimately regains a state of perfect health.*

The strong tendency of chorea to relapse will be mentioned further on.

Pathology.—The nature and causes of chorea are so intimately connected together that it is impossible to discuss the one apart from the other. They involve problems which are of great interest, and have important bearing upon the ætiology of neuroses in general.

In the first place, there are still differences of opinion as to whether the seat of the disease is in the spinal cord or in the brain. When the functions of nervous centres in the cord were first discovered, and when it was found that frogs and other animals could perform co-ordinated movements after removal of the cerebrum, it was natural that attempts should be made to refer to disorder of those centres all affections of which the main symptoms are irregular motions of the body and limbs. Thus Romberg, writing in 1851, placed chorea among the "spinal spasms;" and so recently as 1873 Jaccoud defended a similar doctrine in an elaborate argument. In England, however, the opinion has for some years prevailed that the disease is seated in the sensori-motor ganglia, at the base of the brain, and especially in the corpora striata.

In favour of the spinal theory of chorea, certain experimental results have been adduced. Dogs are liable to a similar complaint, and Chauveau conceived the idea of cutting through the cord close to the skull during the progress of canine chorea; he found that after this had been done the movements went on in exactly the same way as before, the spasmodic contractions of the diaphragm being in one instance sufficient to keep the dog alive for three hours. In two other experiments artificial respiration had to be maintained; but the result was the same as in the first observation, so far as concerned the choreiform spasms. Moreover, a second division of the cord, in the lower dorsal region, put an end to the motions in the tail and in the other parts beyond the section. Chauveau's experiments have been repeated by Legros and Onimus; and they have ascertained, in addition, that by irritation of the posterior columns of the divided cord the spasms were increased, while they were arrested by complete section of the same structures.

It is, however, now ascertained that canine chorea is not identical with the disease of that name in man,† and, even if it were, there remains the question, whether in the human subject the higher nervous centres do not assume functions which in brutes are performed by lower ones. English pathologists have been able to make out a strong case in favour of their own

* Trousseau, however, speaks of children who have never again shown the same degree of intelligence as before; von Ziemssen says that slight defects in the co-ordination of the movements, a precipitancy in the performance of certain manual actions, or a tendency to facial grimaces, may persist for years or even be permanent; and Dr Radcliffe is inclined to think that chorea is apt to be followed by other neuroses, particularly epilepsy, at a later period of life. Dr Bristowe mentions a case in which there was a degree of rigid flexion of the hip- and knee-joints, with overlapping of the knees from preponderant action of the adductors of the thighs, and a tendency to talipes equino-varus,—conditions which seemed to him to indicate degenerative changes in the lateral columns of the cord.

† See Mr Victor Horsley's Lectures ('Lancet,' 1886, vol. i, p. 54).

opinions. Some of the points were stated by Dr Russell Reynolds as far back as 1855. As he remarked, the spasms produced by persistent irritation of the cord are tonic rather than clonic; and it is inconsistent with a spinal origin that the choreic movements are in any degree capable of being controlled by the will, that they are increased by emotions or by voluntary efforts, that they cease during sleep, and that they should be diminished by direction of the patient's attention to other objects. In addition, Dr Broadbent ('Brit. Med. Journ.,' 1869) has insisted on the fact (which Romberg had previously observed) that tickling the palm of the hand or the sole of the foot of a child affected with chorea leads to no increased spasms; on the contrary, it is borne without difficulty, and the excitability to reflex actions sometimes seems to be less than in health. Another point on which he lays still more stress is that the spasms are so often unilateral. An affection of one half of the spinal cord throughout its whole length, from the crus cerebri downwards, without implication of the other half, is, he declares, scarcely conceivable. Moreover the improbability of such a localisation of the disease is increased by the fact that the muscles of the face and trunk are bilaterally affected, these very muscles being liable to be set in action on both sides by stimuli derived from a single corpus striatum, whereas there is no reason to suppose that disturbance of one half of the cord could affect them in a similar manner. Lastly, the fact that the mental faculties are so frequently impaired in severe cases of chorea would naturally incline one to localise the disease as near as possible to the hemispheres.

Dr Dickinson made a series of anatomical investigations in fatal cases of chorea ('Med.-Chir. Trans.,' 1876), from which it would appear that certain morbid changes, consisting of congestion of the vessels, of periarterial degenerations, and of minute spots of sclerosis, are discoverable in the upper regions of the spinal cord, as well as in the lower parts of the brain. Even if the constant occurrence of the appearances which Dr Dickinson has described should be fully established, it would still be a question whether they are not merely secondary effects of the disease. Whatever may be the starting-point of the choreic spasms, one cannot doubt that all the nervous structures which lie between that point and the muscles must have their functional power strained to the utmost during the continuance of such violent movements; and therefore we might expect them to exhibit degenerative changes. It is important to note that Dickinson's cases had all reached an advanced stage. Moreover, it is clear that the persistence of the morbid changes which he describes is compatible with the subsidence of the spasmodic movements and the restoration of health. For in one patient who had twice before had chorea (the last time having been a year previously), the duration of the fatal attack was only thirteen days; and yet changes of old date—periarterial degeneration and scattered spots of sclerosis—were found, besides recent congestion of the cord and basal ganglia.

On the whole, then, the corpora striata seem to be a more probable seat of chorea than the cord—one when the disease is unilateral, and both when all the four limbs are affected.

Another possibility, however, is that the seat of the "discharging lesion" in chorea is the motor region of the cerebral cortex, and many of the objections to the other proposed localities do not apply to this—partly perhaps because its functions are still imperfectly known.

The next question is as to the nature of the anatomical change. Dr Broadbent maintains that the spasmodic movements of chorea indicate that

the functions of a particular part of the brain are deranged. To quote his words, chorea is "a symptom, not a disease. It has been called an insanity of the muscles; it would be better designated a delirium of the sensori-motor ganglia, since it bears the same relation to those parts that the delirium which may occur in a variety of maladies bears to the cerebral hemispheres."

Now, it is possibly true that choreiform spasms may accompany different morbid states of the nervous centres. But it is no less true, and far more significant, that the disease described in the preceding pages as chorea is not met with as an accidental complication of other maladies, but occurs in a particular class of patients, and under conditions peculiar to itself.

Dr Sturges, in his interesting 'Lectures on Chorea' (1877), points out with much acumen how choreic movements find a parallel in the nervous twitchings of mental embarrassment or the restless and purposeless movements of a fidgety child. Yet, admirable as is the critical and negative part of his remarks, it remains true (1) that if a functional disease, the symptoms of chorea must yet depend on functional disturbance (*i. e.* disordered nutrition from irregular supply of blood, or from some poison, or from a molecular change of other origin) which affects one part of the nervous muscular apparatus and not another. Syncope results from anæmia of the cerebrum, not of the liver; tetanus from strychnia affects the cord, not the bulb; and epilepsy depends on some unknown minute derangement in the cells of the cerebral cortex, not in those of the retina. Our business is to fix the "seat" of a disordered function as much as of an impaired structure. (2) It remains true that, while no line can be drawn between health and disease, or between the gravest premonitions of an impending malady and its slightest early symptoms when developed, we must nevertheless recognise certain limits beyond which slight or recoverable deviations become serious enough to threaten comfort or life, or where they lose the accidental character of individual variation and assume the constant and common characters of "recurrent concomitant symptoms" (*Symptomencomplex*). We then know that a disease is before us, according to the only reasonable definition of the word; a condition which has to be understood and treated by a skilled adviser. (3) The fact that an excitable and restless child may often be seen to make movements like those of chorea only proves that choreic spasms are physiological; that the "disease" is an exaggeration and perversion of the action of natural nervo-muscular mechanisms. So the diurnal variations of temperature in health are preserved in pyrexia; so the several primitive layers of the embryo maintain their peculiarities when they give rise to morbid growths; and so the reflex spasmodic neuroses described in the beginning of the present chapter are only perversions of normal excito-motor functions. (4) Like other diseases, chorea has its own natural history, its beginning, middle, and end, its proclivities, and its antipathies. In fact, according to the principles laid down in the first chapter of this book, there is scarcely a member of the whole nosology which better deserves to be called "a disease" than St Vitus's dance.

Sex.—Chorea is much more common in *females* that in males; and (like hysteria) it shows its predilection for the former sex in the case of children before the age of puberty; but, unlike hysteria, it is much more apt to occur in children than in adults.

Tabular statements in regard to these points have been published by the writer in the nineteenth volume of the Third Series of the 'Guy's Hos-

pital Reports.' He found that among a hundred and fifty patients 42 were males and 106 females. These numbers were compiled by Surgeon Manser in 1873. Dr Halstead found the corresponding figures for 1874—1878 were 43 male to 129 female patients. Dr Goodall, our present Medical Registrar, has been good enough to complete these statistics down to the present time. He finds that in the eleven years 1879—1889 we had in our wards 74 male and 188 female patients with chorea. The late Dr Hughes, among 100 cases, found 27 boys and 73 girls (*ibid.*, Second Series, vol. iv, p. 372), and among 209 cases 42 male and 167 female patients (*ibid.*, Third Series, vol. i, p. 245). So that the proportion in a large London hospital would be about one fourth male to three fourths female cases (228 to 663).

Of 531 cases treated in the Hôpital des Enfans Malades at Paris during twenty-two years,* 138 occurred in boys and 393 in girls, *i. e.* rather more than one to three. (We shall presently see that the excess of female patients is less among those under puberty.) Among 422 children under twelve treated for chorea at Great Ormond Street, Dr Hillier found 122 boys to 300 girls, again rather more than one to three. Among 141 children at the Evelina Hospital, Dr Goodhart had 43 boys and 98 girls. A large proportion of boys was also found by Rufz at the Children's Hospital at Paris from 1824 to 1833 (overlapping the first three or four years of Sée's period at the same institution), viz. 51 to 138; and in Wincke's monograph on chorea published at Leipzig in 1844, the proportion was 117 to 210, or more than half the patients were boys, whose ages ranged from four to eighteen. If we put together the statistics mentioned in this paragraph (statistics which, with the partial exception above noticed in the Paris cases, are independent of each other) we find that the total numbers are—of 1610 patients, 471 male to 1139 female, or a proportion of about 2 to 5.

Among 436 cases of the Collective Investigation Committee the proportion of the sexes was 115 to 322, or again rather more than one to three.

Age.—Chorea is characteristically a disease of childhood, seldom or never seen in infancy, and rare after twenty, except in the case of puerperal or pregnant women. Sydenham's lower limit of "the tenth year" is, however, too high. From the fourth or fifth to the fifteenth year for boys, and to the seventeenth for girls, is the choreic period.

Of 216 patients with chorea observed in Guy's Hospital 187 were between six and seventeen years old. Of *first attacks*, among 322 patients recorded there, only two were two years old, and none under that age. The disorder first appeared in five cases between two and five years of age, in 102 between five and ten, in 134 between ten and fifteen, and in 55 between fifteen and twenty. Only two male patients were over twenty when first affected with chorea, one not yet twenty-one, the other thirty-eight; while there were six young women between twenty and twenty-six.

Of Dr Hughes's hundred patients in Guy's Hospital, only one was under eight years old (a boy of five), thirty-two were between eight and ten, forty-five between ten and fifteen, twenty between fifteen and twenty, one (a young man) was twenty-five, and two young women were twenty-two and twenty-eight. In his second series of 198 cases, nine were between four and eight years old, 148 were between eight and sixteen, and above sixteen there were only four men, aged 18, 20, 21, and 43.

In Paris, Sée found that out of 531 cases of chorea, 453 occurred between six and fifteen; in Philadelphia, Hammond found the proportion 67 out of 82;

* Sée, 'De la Chorée et des Affections Nerveuses,' Paris, 1851.

and in Germany, Rufz gives the corresponding numbers as 180 out of 189.

Exceptions.—Chorea is extremely rare over twenty-five, but besides the well-known liability of pregnant *women* (p. 739), we had what was an unexceptionable case in a man of thirty-eight, and several authentic instances have been recorded of the occurrence of chorea at an advanced age. Among the 439 cases of the Collective Investigation Committee there were only ten above twenty-five years old. Five of these were old women between sixty-three and eighty-six. Dr Graves mentions the case of an apothecary in Dublin who was attacked when seventy years old; Romberg saw chorea in an old woman of seventy-six, which had, however, begun when she was six years old; and Trousseau relates in detail an instance which came under the observation of Dr Henri Roger, in a lady, aged eighty-three, who recovered from the disease in five weeks. Charcot has described *senile chorea* as a distinct variety of the disease, but we may perhaps be allowed a doubt whether all the cases would stand criticism. On the other hand, examples are not altogether wanting of the presence of chorea in new-born infants. Thus Richter is quoted by von Ziemssen as having recorded two cases in each of which a female child was affected at birth, the mother having received a fright while advanced in pregnancy; the infant suffered while awake from clonic spasms, which were absent during sleep, and afterwards ceased almost entirely. A somewhat similar instance is related by Dr Long Fox as having occurred congenitally in an infant born six weeks before the proper time.

Still the fact remains, that in the great majority of cases chorea is a disease of childhood between the ages of six and fifteen years, or between the period of the commencement of the second dentition and that of puberty. The preponderance of females among those who are attacked by it is perhaps due to the sensitiveness and mobility of their cerebral organisation. It accords with this supposition that the children most liable to suffer are those who are delicate and excitable. As to the question whether chorea is especially apt to occur in those who inherit a tendency to the neuroses in general, there is some difference of opinion. Trousseau and Anstie answered this question affirmatively, Sée gave a contrary opinion. We must first agree what maladies we will include under the title. Epilepsy, hysteria, and insanity would be admitted by all; but some would take in infantile paralysis, others tubercular meningitis, or hemiplegia, or idiocy, or tetanus neonatorum—diseases which pathologically are widely different.

Among persons more than seventeen years old the preponderance of females is far greater than it is in children. In Dr Hughes's hundred cases there were seventeen women above the age of sixteen to five men. In the writer's first series there were twenty-one women above fifteen to four men, and in the second series twenty-seven women to four men.

Recurrence.—Another important point in the ætiology of chorea is its liability to recur again and again in patients who have once suffered from it. A large proportion of the patients admitted into any hospital have had the disease once or oftener before. Of 262 choreic patients admitted to Guy's Hospital from 1879 to 1889 inclusive, 102 had suffered previously. The writer has recorded the case of one young man who suffered from chorea every autumn from the age of fourteen to that of twenty-two, and of a girl who was attacked each May, from her eighth year to her fourteenth.

The duration of a relapse is generally less than that of the first illness, but Trousseau mentions some exceptions to this rule.

Mental shocks.—The immediate exciting cause of chorea is often a severe nervous impression such as a fright. Many striking instances of this have been placed on record. Thus Romberg relates the case of a girl, aged ten, who was one morning violently alarmed by a dog which jumped at her and barked, and who was seized with chorea the same evening. Again, von Ziemssen speaks of a boy, aged ten, who was terrified by a shot falling unexpectedly close to him on a field, and in whom the disease reached a great pitch of severity within a few hours. Trousseau gave the case of a girl, aged sixteen, who had been caught hold of by a man as she was going downstairs one evening without a light, and who was so frightened that she had a nervous fit, and from that moment became affected with St Vitus's dance. Bright described the case of a boy who had already recovered from an attack of chorea, and who was sleeping with his father when the latter was seized with a fit of apoplexy; the boy was so alarmed that his disease returned. A child, admitted into Guy's Hospital under Dr Pavy, had been frightened by seeing her brother in flames, ran out of the house screaming, scrambled over three walls, took refuge in a neighbour's house, and was brought home and put to bed. Her mother at the time noticed a peculiar twitching movement about her face and irregular motions of her limbs; next morning she was unable to stand, and chorea quickly developed itself.

There is no doubt that much exaggeration has prevailed in regard to the association of chorea with mental impressions, and that parents often jump too hastily at conclusions with respect to the "causes" of this as of most other maladies. But the cases just quoted seem to be beyond dispute, and they afford good grounds for supposing that the same cause has really been in operation in other instances where a longer interval has elapsed. Dr Hughes ('Guy's Hosp. Rep.,' 1856) related a fatal case in which the symptoms were slight when the patient was admitted, but became suddenly aggravated in consequence of a fright.

In other instances chorea is apparently the result of *imitation*. It has long been taught at Guy's Hospital, both by Dr Addison and by the physicians who have succeeded him, that not more than one or two patients affected with this disease should be placed in the same ward with other children, lest they should copy it. But it does not appear that any of the sisters or nurses remember an instance in which this has occurred. Some examples of the occurrence of chorea in an almost epidemic form have been placed on record, of which the most striking appears to be that related by Bricheteau. At the Necker Hospital one afternoon a young girl was admitted, suffering severely from the disease; in the evening a patient already in the ward, who had previously had chorea and was suffering from hysteria, began to exhibit choreic movements, and in twelve hours had to be tied down; next day two other cases occurred, and within the four following days five more, making eight in all: the disease might probably have spread still further had not the patients been from that time isolated. But might not this have been hysteria simulating chorea?

Pregnancy.—Another condition which plays an important part in the causation of chorea in girls after the age of puberty and in young women is *pregnancy*. Dr Barnes has collected ('Obstet. Trans.,' vol. x) a series of fifty-eight cases of this kind. The period of gestation at which the spasmodic movements are most apt to begin is from the first to the third

month, but sometimes it is much later; and two instances have been recorded in which they followed parturition. First pregnancies are much more often accompanied by chorea than subsequent ones. This of itself suggests that one element in the production of the disease may be the emotional excitement which necessarily arises in a woman who finds herself for the first time pregnant, and the suspicion is confirmed by Dr Wilks's observation that a large proportion of those who are attacked are unmarried girls, to whom their condition is one of shame and distress. Thus a connecting link is established between the chorea of pregnancy and that which occurs under other circumstances; and a still stronger one is the fact that in a considerable number of cases the patient has already had the disease on one or more occasions at an earlier period of life. Among the sixty-six cases already referred to there were fourteen in which previous attacks had occurred.*

Rheumatism.—So far the causal relations of chorea differ but little from those of the neuroses in general. It may be added that, according to Trousseau, chlorosis and anæmia are among the conditions which dispose to its development. We now pass to an entirely different predisposition which applies to this, but to no other nervous disease,—rheumatic fever.

As far back as 1811 rheumatism was stated to be one of the causes of chorea, in the Syllabus of Lectures on Medicine delivered at Guy's Hospital, by Drs Babington and James Currie, "It often follows rheumatism, and these two diseases often come on alternately." Dr Bright (whose testimony carries back the tradition nine years earlier) was himself convinced of the relation.†

Beside Bright and his pupils, the younger Babington and Hughes, Dr Copland and Sir George Burrows were early advocates of the belief that there is a real connection between chorea and acute rheumatism, and that the latter predisposes to the former. See introduced the same theory into France, and it is generally acknowledged in Germany and America. The connection is all the more probable because it is quite unexplained, and supports no theory of either disease.‡

The close association between chorea and rheumatism is shown by the fact that these two disorders are the chief and almost the only causes of valvular endocarditis. Out of over eighteen fatal cases of chorea which occurred in Guy's Hospital between 1848 and 1876, in only one was endocarditis absent; and that the frequency of its occurrence was not dependent merely upon the severity of the chorea is evident from the fact that in five of these cases the patient's death was due to some complication or intercurrent disease. The same conclusion is confirmed by the frequency with which chorea and rheumatism occur in the same patient; a child who has had rheumatism falls ill with St Vitus's dance a few years afterwards, or *vice versâ*; or slight choreic movements appear in the course of a rheumatic attack, or rheumatic synovitis recurs in the course of chorea.

* See also Dr Lever's paper ('Guy's Hosp. Rep.,' Second Series, vols. v, p. 3, and vi, p. 233).

† He thought that an intervening link between the two disorders was to be found in the presence of pericarditis, from which he imagined that irritation was transmitted to the nervous centres, just as in other cases it might be communicated from the intestines or the uterus. In support of such a view there certainly is a case recorded by Dr Wilks, in which pericarditis caused by renal disease was accompanied by choreic movements. That case, however, is at present unique; and inflammation of the pericardium is after all present in very few cases of chorea.

‡ The only plausible arguments against it are forcibly put by Dr Sturges ('Chorea and Whooping-cough,' p. 16).

Statistics are as follows:—Among the patients of Guy's Hospital, (*a*) in the late Dr Hughes's first series ('Guy's Hosp. Reports,' 1846), special inquiries were made in fifty-eight cases; there was a cardiac murmur in nine, and a history of rheumatism without bruit in eight more; (*b*) in his second series, compiled by Mr Burton Brown (ibid., 1855*), special inquiries were made in 104 cases, and in eighty-nine of these there was either bruit or rheumatic history; (*c*) in the series of 150 compiled by Mr Manser, and published in 1874 (ibid., Third Series, vol. xix), forty-two had suffered from rheumatism, and in three of these rheumatic fever supervened while they were under treatment for chorea; there was a bruit in fifty-nine, none in eighty; (*d*) in the fourth series, of 163 cases compiled by Mr Halstead, fifty-three had had rheumatic fever or distinct pains in the limbs, believed to be rheumatic, and in thirty-five of them the rheumatism preceded the chorea by less than six months; there was a bruit in sixty-one, none in 111.

Of Prof. Sée's 128 cases, sixty-one had probably had rheumatism.

Of Dr Sturges' 100 cases, only twenty had had rheumatism.

In 104 consecutive cases of chorea at the Westminster Hospital Dr Donkin found twenty-seven cases of previous rheumatism.

Of Dr Goodhart's 130 cases (collected from several sources) eighty-nine were on positive evidence believed to have had rheumatism.

Of Dr Angel Money's 214 cases (also collected) thirty-three had had rheumatic fever, twenty-three had had rheumatism, and nine were doubtful.

In 172 cases of chorea at the London Hospital Dr Stephen Mackenzie found a history of distinct rheumatism in forty-seven ('Trans. Int. Congr.,' 1881, vol. iv, p. 97).

The Collective Investigation gave 116 instances of precedent rheumatism (excluding mere "rheumatic" pains) in 439 cases of chorea.†

Two children in the same family often have chorea, but we rarely find that the parents of a choreic child have themselves suffered from the malady when young. This is the same kind of "transverse" hereditary relation which we observed to obtain in certain other maladies,—Friedreich's ataxia (p. 539), Thomsen's disease (712), and some forms of muscular atrophy.

Embolic theory.—Attempts have been made to explain the connection between chorea, rheumatism, and cardiac disease upon a theory which, although it has had the support of some distinguished observers, does not appear to be well founded. Its author was the late Dr Kirkes. Starting from the frequent association of endocarditis with chorea, he suggested that the cause of the spasmodic movements might be the introduction of inflammatory products and fibrinous particles from the diseased valves into the blood, and the consequent disturbance of the parts supplied. Dr Hughlings Jackson and Dr Broadbent have expressed a similar view in a more definite form, maintaining that the cause of chorea is embolism of minute arteries in one or both of the corpora striata.

A few observations have since been made by different pathologists which have been thought to corroborate Dr Jackson's theory. In a very severe case, attended with maniacal symptoms, Dr Tuckwell ('Med.-Chir. Rev.,' 1867) found at the under and outer aspect of the right hemisphere a large red patch of softening, affecting to some extent the white as well as the

* The first volume of the Third Series was published in 1855, not 1856, as stated by von Ziemssen, Bd. xii B, S. 443.

† See also statistical papers by Dr Herringham and Dr Archibald Garrod in the 'Medico-Chir. Trans.,' vol. lxxii, pp. 117, 145.

grey matter; and a branch of artery which ran straight into it contained a small, white, tough, fibrinous concretion, tightly wedged into an angle of bifurcation, and connected on all sides with long black coagula, extending into the trunk of the vessel and its branches. On the outer aspect of the same hemisphere was a similar patch, but smaller, and limited to the superficial cineritious substance of the convolutions; in this nothing like an embolus was discovered, but the parts had been cut through in various directions before the dissection of the vessels was commenced. In another case of very acute chorea, which terminated fatally by hæmorrhage into the brain, Dr E. L. Fox ('Med. Times and Gaz.,' 1870) believed that he detected microscopic emboli in the vessels of the corpus striatum.

Dr Angel Money has endeavoured to produce chorea in monkeys and cats by injection of starch-granules or insoluble salts into the cerebral arteries, and the results will be found in the 'Medico-Chirurgical Transactions' for 1885; see also 'British Medical Journal,' July 17th, 1886.

But is it possible to determine whether clots in minute cerebral arteries are of *ante-mortem* formation, still more whether they entered the vessels from below, instead of being formed *in situ*? Moreover, the minute, firmly adherent vegetations which are found on the valves in chorea, do not seem at all likely to be detached and carried away by the blood-stream. If they were so liable to be washed off, what could prevent some of them from being carried into the spleen and kidneys, and producing infarctions there? but such appearances have never been discovered in any of our fatal cases of chorea. Again, as Dr Bristowe remarks, it is difficult to understand the limitation of chorea to the limbs of one side on the embolic theory, since a shower of minute emboli must be supposed to enter the arterioles of one corpus striatum only. We are familiar, however, with endocarditis in which vegetations are carried from the diseased valves, and cause embolism in the brain and in other parts; and in these cases chorea never develops itself.

But the strongest argument of all is the above-mentioned relation of chorea to *mental shocks*. Some writers have supposed that the cases in which the disease follows a fright are distinct from those in which it is associated with endocarditis; but this is certainly not the fact. On the contrary, as already stated, vegetations are found on the cardiac valves in all fatal cases, almost without exception; for instance, a child died under Dr Wilks's care who was attacked by chorea after being terrified by the gunpowder explosion at Erith, and *post mortem* the mitral valve was found inflamed. Now, it is obvious that the disease cannot possibly have two different exciting causes in a single case. It cannot be at one and the same time the result of a mental shock and of embolism of several minute cerebral arteries. In such cases we must admit that the endocarditis is an effect of the chorea.

Still it is not to be denied that any view of chorea presents difficulties. It is strange that a disease so closely related to acute rheumatism should be excited by a nervous shock; it is still more strange if, when so produced, it should possess a power like rheumatism itself of setting up inflammation of the cardiac valves. No more striking instance could be found of the complicated working of different predisposing and exciting causes, which concur in the ætiology of the neuroses, and of many other diseases.

Treatment.—This is a very difficult question; for chorea offers peculiar obstacles to the satisfactory investigation of the action of remedies. Many of the severer cases tend naturally to a more than usually rapid recovery;

and in other instances (as Dr Wilks has proved) the being admitted into the ward of a hospital and kept in bed is of itself sufficient to bring the complaint quickly to a termination. Under either alternative, the medicine which may have been prescribed is apt to get undue credit. Lastly, in the great majority of cases, *chorea subsides of itself after eight to twelve weeks*, under whatever treatment. Now, the method usually adopted is to give one drug for three or four weeks; if that fails, to change it for another, which is continued for about an equal period of time; and, if there is still no result, to begin the administration of a third. The result necessarily is that even if all these medicines are really equally inert they gain very different degrees of credit. The uselessness of the one which is first given is sure to be apparent; but the second runs a chance of apparent success; while the last one is almost certain to acquire the reputation of having cured a case in which its competitors had altogether failed. Yet that very drug, if placed first on the list for a succeeding case, would perhaps show itself as impotent as the others. Probably much of the uncertainty as to the value of remedies in chorea is explicable in this way.

One method of avoiding these difficulties would be to treat a considerable number of cases with some one medicine throughout the whole course of the disease, and then to compare the result with the series of cases related by Drs Gray and Tuckwell, which were allowed to terminate without interference. These observers administered arsenic to fifteen choreic patients; and they state that the average duration of these cases was almost the same as if no medicine had been given. The very volume of the 'Lancet' (1871) in which their investigations are recorded contains reports of twelve other cases by Mr Butlin, treated by Drs West and Dickinson with sulphate of zinc. But it is impossible to compare their results with those of the Oxford physicians. Two of the cases had lasted for so great a length of time before they came under observation (thirteen months and four years respectively) that their introduction would swamp the whole series. Yet these two only present in an extreme form difficulties which belong in a less degree to all the other cases, every one of which had lasted for several days, and many of them for some weeks, before the administration of the medicine was commenced. It is not easy to see how one could avoid this source of fallacy, except by confining one's observations to the children in one particular school, where a uniform treatment could be employed from the very beginning of the disease. So that it is almost impossible to obtain statistical proof of the value of medicines in the treatment of chorea.

But there is very strong evidence, of another kind, in favour of at least one remedy. Very protracted cases, which had resisted all other methods of treatment, have sometimes been found to yield in a very short space of time to *arsenic*. Some striking examples of this are recorded by Romberg.

One is that of a girl, aged eleven, who had for eight years suffered from intense chorea, affecting especially the right half of her body. All drugs had been found useless until she began to take Fowler's solution; in about two months there was a marked improvement, and at the end of two months more she had entirely recovered. Another patient, a girl aged ten, had had the disease two years; arsenic was prescribed, and within three weeks the symptoms presented a marked abatement; and ten or eleven weeks afterwards she was discharged cured. A third instance is that of a girl, eight years old, who for six months had been the victim of chorea to such an extent

that she could not walk, nor stand, nor speak articulately. The remedies which had been tried had failed; Fowler's solution, in doses of four drops three times a day, established a cure in eight weeks. So far as appears, the only objection that can be offered to these cases is that it is not distinctly stated whether or not the patients, while the medicine was being given remained otherwise under the same conditions as before.

Another argument in favour of the effect of arsenic and other drugs upon chorea is derived from our experience among out-patients. There the children have none of the great advantages of quiet, careful feeding and nursing which cure many cases of chorea when admitted to a hospital ward. No change in their condition is made, except the administration of a drug; and when under this treatment a complaint which, in some cases, has lasted for weeks disappears, we can scarcely help attributing the cure to the remedy.

Most observers are of opinion that others of the so-called nervine tonics are also useful. Thus the *sulphate of zinc* has for many years been largely used at Guy's Hospital; one-grain doses of it used to be given at first, which were gradually increased until the patient took a scruple or more. It seems more advisable to begin with a larger dose—for instance, with five grains. This seldom causes nausea or sickness more than once or twice. Another drug which once had a great reputation is the *carbonate of iron*.

Salicyl compounds have been lately used, and, in some cases, with seeming success ('Brit. Med. Journ.,' 1887, vol. i, p. 436).

Static electricity, used in the old-fashioned way, was formerly much used at Guy's Hospital by Addison, Golding-Bird, Gull, Hughes, Babington, and Lever ('Guy's Hosp. Reports,' Series I, vols. ii, vi, and vii; Series II, vol. viii), but it has long been given up. Galvanic and faradic electricity have likewise been tried, praised, and abandoned.

There is reason to believe the milder cases of chorea may to some extent be checked by gymnastic exercises, by military drill, or by the use of a skipping-rope. French physicians have laid stress upon this method of treatment, and it has had undoubted successes.

On the other hand, one sometimes has to deal with cases which are so severe that the administration of nervine tonics, requiring time for their operation, is obviously inapplicable, because the patient is in imminent danger of dying within two or three days. There is the greatest difficulty in determining the value of remedies in cases of this kind. Probably death is sometimes inevitable. But even then the inhalation of *chloroform* gives great relief to the patient's sufferings; and if there be a chance of recovery it may do something towards economising his strength. It also saves him from the sores which would form over the bony prominences if the movements were uncontrolled. In cases which are a little less severe, *chloral* appears to be the best medicine. Several writers have related cases in which it seemed to be effectual; not the least striking is one of Dr Gairdner's, of a girl who took a drachm of it by mistake, and was poisoned, but who on her recovery was found to be cured. Again, the muscular depressants—conium and the Calabar bean—have sometimes been employed. At one time the author prescribed the succus conii in considerable doses for several choreic patients, and some of these recovered more quickly than was expected.

A point of great importance in very severe cases is that the patient should be kept well supplied with food; nutrient enemata ought to be administered frequently; and probably it is right to give full doses of alcohol.

CONGENITAL REFLEX SPASMS.*—We have at the present time (April, 1890) lying in Philip Ward a boy about eight years old who "makes faces" much as a child with chorea does; but on pulling down the bedclothes it is plain that the case is not one of ordinary chorea, for the movements of the limbs are slower, and the spasms are tonic as well as clonic. The arms are extended and the hands go through slow twisting movements, not choreiform, but exactly what we have before described under the term "athetosis" (*supra*, p. 701). The legs are thrust out and very stiff, so that the trunk can be lifted on raising them: the adductors and extensors are in tonic spasm. The feet do not show the characteristic attitude of tetany. The spasms are much increased when the visit to the ward brings a number of strange faces round the bed, but they do not disappear when he is quite undisturbed, and even in sleep the child lies always on one side, with his legs and arms thrust out in front of him to their full length. Handling the muscles increases the rhythmic as well as the spastic contractions, and if they are continued, the child sometimes cries, but it does not appear that he suffers much pain even then. He can put out his tongue; there is no squinting or nystagmus; the functions of the bladder and rectum are normal. He is well-grown, rather slender in build, but not ill-nourished; and there is no deformity of the head, no curvature of the spine, and no club-foot. A normal knee-jerk can be detected with some difficulty: there is no clonus. He can talk, but almost unintelligibly; and though he understands what is said, he is obviously behind his years in intelligence. He is docile and good-tempered, but timid. On further inquiry we learn that this condition is congenital, that he "could not move at all" as a baby, and could not talk till he was much older than usual, and that at one period he was "subject to fits." Lastly, Dr Todd, of Brigg, Lincoln, who brought him into the world, informs us that the labour was unusually protracted, and that there was a well-marked caput succedaneum when he at last was born.

The clinical features of this case, while agreeing with those of a reflex spasmodic neurosis, are those which have been described as congenital choreiform spasms; but the presence of a definite anatomical lesion is rendered almost certain by the absence of family predisposition, and the history of the patient's birth.

Such cases were observed by Dr Sarah MacNutt, an American physician in 1885, as occurring in obstetric practice and due to meningeal hæmorrhage. Many prove fatal in infancy, but in others the hæmorrhage is followed by circumscribed atrophy of the cortex, either from pressure of the clot, or perhaps more likely from disturbance of the nutrition of the convolutions. Why such atrophy produces spasm instead of paralysis, why it is a "discharging" instead of a "destroying" lesion, is hard to say. It almost seems as if there were abolition of inhibitory motor centres in the cortex, which allows co-ordinated reflex movements to take place like those of a decapitated frog or pigeon. See Dr Osler's 'Cerebral Palsies of Children.'

The spasms are not always so general in these cases; they may affect one side, or both legs, or one limb only. In some cases clonic spasms predominate, bringing them nearer to "hammer-spasms" and "histrionic spasms;" in others the resemblance to primary spastic paraplegia is very close; in

others again, that to chorea. The long duration of the malady, the more or less deficiency of speech and intellect (not more, however, than in certain cases of chorea while they last), and the history of the origin at birth are the diagnostic characters to dwell on.

The prognosis is unfavourable, but some of the patients gradually acquire increased power of grasping objects, of talking, and even of locomotion.

No treatment is promising. We have tried physostigma, bromides, and chloral hydrate without much benefit. Dr Gowers, who has observed more than thirty cases of this curious malady, says that electricity however applied is useless.

Hereditary chorea in adults—Huntingdon's chorea.—In exceptional cases chorea appears to be hereditary in certain families, and passing over the earlier years of life to make its appearance at about the age of thirty. The clonic spasms begin in the face, and gradually spread to the arms and the legs, continuing for several years. The gait acquires a peculiar hasty and hesitating character, and the speech becomes intoned. Not only is the malady long continued, but it has usually ended in mental decay, and at last in death. This variety of spasmodic neurosis is obviously different from true chorea in its course as well as in its pathological relations. Huntingdon's cases were observed in Long Island, New York. Others have been described in this country, and Huber has recorded a remarkable case which occurred in Eichhorst's practice at Zürich.

*Friedreich's spasms.**—Under this name a spasmodic disease in an adult patient was described by Friedreich in 'Virchow's Archiv' (vol. lxxxvi), and since by Hammond. Gowers considers that the malady is perhaps intermediate between chorea and facial spasm or torticollis, and more nearly allied to senile chorea than to any other malady.

Dr Weir Mitchell's "*habit-chorea*" applies to those involuntary tricks, which are truly spasmodic neuroses. They begin in childhood, but often persist in adult life. Blinking with the eyelids, tapping with the foot, suddenly twisting the head or jerking the hand, hiccough, choking or snorting at intervals, sniffing lecturers and smiling preachers—all these are examples.

Dubini's disease.†—This name has been given to an obscure malady consisting of choreiform spasms which has been observed in Italy, and is supposed to depend upon malarial influence. The suddenness of the spasmodic shocks, the fact that most of the patients are of advanced age, and that some cases are fatal, separate it from true chorea. There are, moreover, tonic paroxysms and epileptiform fits. It was first described by the late Dr Dubini, of Milan, about 1850.

* *Synonyms.*—Paramyoclonus multiplex—Myoclonus multiplex—probably identical with the Convulsive tremors described by Pritchard in 1822.

† *Synonyms.*—Electrical chorea—Typhus convulsivo-cerebralis—Myelitis convulsiva.

THE PAROXYSMAL NEUROSES

Paroxysmal vertigo—Auditory vertigo and Menière's disease—Somnambulism—Catalepsy—Night terrors.
MIGRAINE—*Nomenclature—Symptoms—Pathology and causation—Treatment.*

WE have now to consider a remarkable series of affections, which, although they differ widely in their symptoms, nevertheless have close mutual relations, and present many points of resemblance, both in their causes and in their circumstances.

The chief among them are Epilepsy (including both the *petit mal* and the *haut mal*), Catalepsy, Somnambulism, Migraine, and Paroxysmal Vertigo. With these several others might be included:—Tic douloureux, paroxysmal Insanity, Angina pectoris, paroxysmal Gastralgia, spasmodic Asthma, spasmodic Croup, and Laryngismus stridulus. For reasons of convenience, however, these are treated elsewhere.

No modern writer has so clearly pointed out the relations of these various diseases to one another as Dr Edward Liveing, who, in his treatise on 'Megrim or Sick Headache,' shows how in the same patient they are often transformed one into another in the course of time. Most other writers have dealt with them from too narrow a standpoint; they have included too much under a single affection, as epilepsy.

Common features of the group.—The disorders in question all occur in paroxysms, and at more or less regular periods. Most of the patients are in perfect health during the intervals. We may distinguish them as "paroxysmal neuroses;" or, adopting the happy phrase of Dr Liveing, as "nerve-storms."

These diseases for the most part are *innate* and *hereditary;* and in different members of the same family the inherited tendency may show itself in different ways—one child being epileptic, another asthmatic, a third subject to megrim, and so on.

In more than one of the affections now to be described, each attack is made up of a regular *succession* of phenomena. In migraine it often begins with a peculiar affection of sight; afterwards follow in turn numbness of the fingers, vertigo, headache, vomiting, and sleep. In epilepsy there is perhaps first a sensation passing up from one of the limbs to the head, and then successively complete insensibility, a general tonic spasm, a series of clonic

convulsions, and prolonged stupor. We can hardly fail to regard such seizures as dependent upon the gradual extension of some molecular change from one part to another of the nervous centres.

Other points in which most of these affections agree is that the attacks gradually *culminate* in a certain pitch of intensity, and then subside; and again that there is a kind of *compensation* between the frequency and severity of the paroxysms, for a slight one is followed by another at a short interval, while a severe seizure may ensure a long period of repose.

The paroxysms are often traceable to *causes* similar for all the members of this group. In describing the different varieties of "nerve-storm," one has again and again to mention gastric disturbance, irritation of the brain from dentition or disease of the teeth, exhaustion from deficient food or excessive bodily exercise, disorders of the sight, smell or hearing, as giving rise to a first attack, or to the succeeding ones also. Many of these neuroses bear a relation to puberty and the other great epochs of life, to the appearance of the catamenia in women, to pregnancy or to the puerperal state. Most of them are apt to break out for the first time at some particular age—migraine and epilepsy about puberty, laryngismus stridulus and spasmodic croup during infancy, and tic douloureux in later life; while, as we have seen, tetany and chorea are diseases of childhood. Some of the paroxysmal neuroses tend to disappear spontaneously when a certain period of life is reached; thus migraine often ceases to recur after fifty.

Another feature which is common to the paroxysmal neuroses is their tendency to undergo *metamorphosis* in the same patient as time goes on. This is particularly the case with epilepsy; its attacks are liable to be replaced by vertigo, catalepsy, mania, or other forms of nervous disturbance. Indeed, if we had convenient English names for the *petit mal* and the *haut mal*, it would be well that they should be described separately, for their relation to one another is not very much closer than to some of the other affections treated in this chapter. The connection between migraine and epilepsy is certainly much less intimate.

It would, however, be incorrect to represent the paroxysmal neuroses as an isolated group, for there are unmistakable evidences of relation between Epilepsy on the one hand, and Chorea, Hysteria, and Insanity on the other. But, on the whole, Megrim, Vertigo, and Epilepsy may provisionally be grouped together.

EPILEPSY.*—*Definition.*—Convulsions which closely resemble the fits of epilepsy may accompany the onset of variola and other exanthemata in children; they occur shortly before death by hæmorrhage; they result from Bright's disease and from the puerperal state; and we have seen that they are caused by various organic affections of the brain.

But, in remarkable contrast with the various cases just referred to—in all of which the fits are accidental, occasional, or solitary,—there are other cases in which convulsive fits, of precisely the same kind, return again and again for years together, and often without being traceable to any cause, except in some instances an inherited tendency to nervous disorder. One cannot but regard such cases as essentially distinct from the others, and

* *Synonyms.*—'Επιλημψία or 'Επίλημψις, a seizure (Hippocrates, Aristotle)—Morbus Comitialis (Seneca and Pliny), so called, according to the grammarian Festus, because the Roman assemblies were broken up if anyone present was attacked by a fit—Morbus sacer (Cœlius Aurelianus).—*Anglice*, Falling Sickness.—*Fr.* Haut Mal.—*Germ.* Fallsucht.

needing a special name; we therefore speak of them as *epileptic*, and call fits which are accidental, secondary, or symptomatic, *epileptiform*; or we may conveniently apply the term "eclampsia" to the latter generally, instead of confining it to the convulsions which are apt to occur after childbirth.

In limiting the use of the word Epilepsy to an idiopathic and recurrent paroxysmal neurosis, one must not imagine an underlying essential disease of which the fits are only symptoms. The fits themselves constitute the disease, the only other element in its definition being the clinical fact that they tend to return at more or less regular intervals for an indefinite length of time. The distinction between *epileptic* and *epileptiform* attacks is not always easily applied. Some cases of very long standing should nevertheless be classed with symptomatic eclampsia rather than with true epilepsy. On the other hand, a single fit, which is never repeated, may belong to epilepsy in the restricted sense of the term, although the tendency to recurrence is overcome by treatment, or is never called into activity.

Epileptic attacks vary greatly in severity. In accordance with the universal practice, we may divide them into two principal groups, the one corresponding to what the French call the *petit mal*, the other to what they call the *haut mal*. These terms have been Latinised as *Epilepsia minor* and *Epilepsia major*, and it would be convenient to adopt similar expressions in English. The *petit mal* is sometimes spoken of as *epileptic vertigo*, but for more than one reason this use of the term is undesirable.

Epilepsia minor.—A paroxysm of the *petit mal*, or minor epilepsy, may be a mere suspension of consciousness, sudden in its onset, and scarcely more than momentary in its duration. For two or three seconds the patient is lost, but he quickly recovers himself, and goes on with what he is doing. Dr Wilks mentions the case of a shopman who often had a seizure of this kind while serving a customer, and who believed that no one noticed it. In some instances such attacks are attended with muscular rigidity. Dr Chambers relates that a well-known lecturer would sometimes be seized while addressing his class, and would stop in the middle of a sentence, remaining perfectly still, with mouth open and arms extended; after a minute or two he would go on just where he left off without knowing that anything had happened. Dr Chambers, indeed, puts this case as one in which the *petit mal* assumed the characters of *catalepsy*, but it does not seem clear that it really deserved that name. At any rate its close relation to epilepsy was shown by the circumstance that this patient afterwards suffered from that disease in its major form.

In other cases, if the patient should happen to be speaking at the time when he is attacked, he loses the thread of his discourse, and afterwards he cannot remember what he was saying. Or he may stagger and lean against something, or grasp at it for support. He may experience a sensation of giddiness and lie down to avoid falling. Dr Wilks mentions one instance in which a little girl would be sitting in her chair stitching, when she would suddenly fall, but before the nurse could pick her up she would be in her seat and again at work. To such cases the name of "epileptic vertigo" would be applicable if there were not another *paroxysmal vertigo*, which does not bear so close a relation to epilepsy (*v. infra*, p. 767). Moreover, some writers call any nervous affection epileptic which recurs in paroxysms.

If we have the opportunity of watching an attack of minor epilepsy we may notice that the patient's pupils become slightly dilated, and that he no

longer seems to be looking at anything. The face often becomes pale, and afterwards slightly flushed. Dr Reynolds says that the pulse may falter and become irregular, and Dr Moxon has observed the same thing; but it is quite the exception.*

In a large majority of cases the so-called fainting fits which are apt to occur in children are really of an epileptic nature.

It is, however, certain that in some instances the circulation in the face and limbs goes on without interruption during an attack of the *petit mal*. Dr Reynolds testifies to this from repeated observations.

Not infrequently an attack, which is in all other respects one of "minor epilepsy," is accompanied by some slight convulsive movement. There is a transient strabismus; the mouth is drawn to one side; the whole head is turned towards one shoulder; or the body generally becomes for an instant rigid. Cases of this kind form links between the two main varieties of the disease, and show how closely they are related to one another. A further proof is the fact that in perhaps the majority of cases in which attacks of the *petit mal* occur again and again, they are after a time replaced by those of the *haut mal*. Or the patient may suffer alternately from the one and from the other.

Prodroma.—Before describing the phenomena which constitute a regular attack of the *haut mal* we must mention certain sensations which some patients experience at the commencement, and which may precede the other symptoms, so as to afford a warning of the approach of the seizure. To all such phenomena the name of *epileptic aura* is commonly given by a convenient extension of its original meaning; it was first applied to a feeling as of a draught of air passing over the surface until it reached the head, whereupon the patient became insensible. Sometimes a creeping or a dragging sensation is experienced, which begins in the fingers of one hand or the toes of one foot, and rapidly moves upwards. Dr Bazire relates a case in which it first affected the wrist, and then extended downwards to the tips of the fingers. Dr Radcliffe had a patient in whom it was a painful sensation, always referred exactly to the foramen cæcum at the base of the tongue. Other cases have been recorded in which an aura has consisted of a painful sensation at the epigastrium, attended with nausea. Or, again, there may be loss of sensation in one side of the face or in one limb. Nothnagel mentions an instance in which numbness always began in the right shoulder and side of the head, and spread downwards into the right arm, the right leg, and the right half of the body. When an aura passes up a limb its path seldom corresponds with the course of any particular nerve. In some rare cases it seems to start from the seat of a former injury. Sir Thomas Watson quotes a case in which it proceeded from an old cicatrix in the side. Dr Wilks states that a girl under his care localised her aura in a sore spot on her face, and that her father assured him that the application of laudanum to that part would sometimes arrest the fit.

* Some years ago, while I was one day listening with the stethoscope to the heart of a man whom I had never seen before, its beats suddenly ceased. I looked up and saw that his face had turned deadly pale. He said that he was going to faint, and reclined back on the chair from which he had risen. I could feel no pulse at his wrist, and for an instant I thought that he might be going to die, but I had hardly time to ring my bell when the colour returned to his face, and I found that his heart was beating again. Presently there was a little twitching of the muscles in one or both hands. In a minute or two he was able to tell me that he often had "fainting fits," and that some years back he had been subject to epileptic seizures. It appeared clear that the attack which I had witnessed was one of minor epilepsy.—C. H. F.

In other instances it would seem that an epileptic aura is due to an affection of the vaso-motor nerves of some part of the body. The patient perhaps experiences a sensation of coldness or weight in a limb; and the part is found on examination to be pale and cold to the touch, and to have its sensibility distinctly blunted. Trousseau says that when an aura occurs in a finger it is sometimes a little swollen, so that the rings on it which before were loose suddenly become tight.

In other cases, again, an epileptic attack is preceded by a profuse secretion of tears, or of saliva, or of sweat, as in several cases that have come under Nothnagel's observation.

What has been termed a "motor aura" may take the form of tremor or of slight spasms. The eyelids may twitch, or some muscles of the face or of a limb; or more complex movements may take place, the patient turning round, or running some distance.

Again, the epileptic aura may be referred to one of the special senses. Joseph Frank is said to have met with an instance in which it always took the form of a sweet taste. Still odder is Dr Gregory's case, quoted by Watson, of a man who always fancied he saw a little old woman in a red cloak; she seemed to come up to him and to strike him a blow on the head, whereupon he lost all recollection and fell down. Sometimes the only warning is a vague sensation of fear. Dr Reynolds was told by a gentleman that what always passed through his mind was, "This is what I had foreseen. I knew it would come on here; I ought to have avoided it by remaining away,"—although in reality he had not suspected that a fit was impending.

An epileptic aura may last for a few seconds or for several minutes, or even longer. Nothnagel mentions that when it has lasted more than ten minutes, he has been able to ascertain that there was distinct loss of sensation in the part affected. Sometimes it occurs and passes away without being followed by a fit. In one of Nothnagel's patients a vaso-motor aura in one leg sometimes occurred six times daily, whereas she had only about one epileptic attack in a week.

*Symptoms of the fit.**—An attack of the *haut mal* begins by the patient suddenly—almost instantaneously—falling unconscious, with strained and rigid muscles. As he is seized, he may utter a sharp shrill cry; or he may be perfectly silent, the respiratory movements being arrested by spasm; or he may emit a smothered groaning sound. In many cases the face becomes pale; but in some its colour remains unchanged. The heart goes on beating, and the carotid arteries continue to throb. But the radial pulse is sometimes imperceptible, this being probably due to the contracted state of the muscles of the arms.

The *tonic spasm* which occurs at this period of an epileptic or other kind of fit is peculiar; it usually affects one side of the body more powerfully than the other; the head is turned round towards one shoulder, and the eyeballs are strained in the same direction. The pupils constantly become dilated; but Dr Reynolds says that in one instance he observed a momentary contraction before dilatation began. They are generally, if not always, insensible to light. Touching the conjunctiva commonly excites no reflex movements, but according to Romberg it is sometimes followed by closure

* "Inter notissimos morbos est etiam is qui *comitialis* vel *major* nominatur. Homo subitò concidit: ex ore spumæ moventur: deinde interposito tempore ad se redit, et per se ipse consurgit. . . . . Modò cum distentione nervorum [*i. e.* convulsions] prolabitur aliquis, modò sine illâ" (Celsus, 'De Med.,' lib. iii, cap. xxiii).

of the lids; this observer also states that sprinkling the surface of the body with cold water may in some cases cause shrinking movements. Soon the face flushes, and acquires a dull red or dusky hue. This appears to be in great measure due to the fact that the large veins of the neck undergo compression, and that the flow of blood through them is interrupted by the spasmodic contraction of the sterno-mastoideus and neighbouring muscles. Spasm of the glottis seems also to occur.

The stage of tonic spasm may last only two or three seconds, or it may be prolonged to thirty or forty seconds. Trousseau says that in some rare cases it extends over two or three minutes—in fact, until the patient dies asphyxiated. It is followed by a stage of *clonic spasms*. These also are generally more marked on one side than the other. The fingers of one hand are alternately flexed and extended; the like movements simultaneously occur in the other joints of the arm, and even in the corresponding lower limb, and the eyes are twitched violently towards the affected side. The opposite limbs may escape entirely, or be affected with less powerful convulsive movements. The pupils sometimes oscillate between a state of contraction and one of dilatation. The jaws are forcibly contracted, and the tongue is often caught between the teeth and bitten on one side. The blood from it is mixed with the saliva that is poured abundantly into the mouth; and a red foam is sputtered through the clenched teeth. The face is now of a livid purple hue. There is often profuse sweating, sometimes urine is passed involuntarily, and emission of semen or defæcation may occur.

This second stage—that of clonic spasm—may last two or three minutes; according to Dr Reynolds, even ten minutes. Trousseau, however, says that it scarcely ever continues more than four or six minutes: as he remarks, one is very apt to be deceived as to its duration unless one reckons the time by a watch. As the convulsive movements pass off they become slightly altered in character. They are no longer wholly meaningless. The patient often draws a deep sigh; he may endeavour to change his position, and may look at those about him with a bewildered or suspicious expression.

When the fit passes off, the patient may at once regain his consciousness; or he may be more or less confused for a time; or, more frequently, he becomes drowsy and passes into a deep sleep or stupor, which may last several hours, and is often attended with guttural stertor. During this time, if he can be roused at all, he is generally irritable and peevish. Slight clonic spasms not infrequently recur.

Even when an epileptic fit occurs during sleep, one can often make out its real nature by the fact that the tongue next morning is found to be sore, or that the urine has been passed involuntarily, or even the fæces. As Trousseau points out, if a patient who had never before had difficulty in retaining the contents of his bladder at night, should now and again find that he has wetted his bed, this mere fact should arouse the fear that he may be an epileptic. Dislocation of the shoulder, discovered on waking in the morning, may signify an epileptic fit during sleep. A similar inference may sometimes be drawn from the presence of minute scattered red petechial spots, like fleabites, which occur chiefly on the forehead, throat, and chest. When these petechial hæmorrhages occur after an epileptic attack in a person who has not before been subject to fits, they may be wrongly regarded as evidence that the patient is suffering from blood-poisoning, or that an exanthem is about to appear. Dr Wilks has recorded a case in which this mistake was made.

Exceptional forms.—An attack of major epilepsy does not always conform strictly to the above description. It is sometimes attended with but slight convulsive movements, or perhaps with none at all. Such cases were formerly described as examples of a form of apoplexy, or as "apoplectiform cerebral congestion" (cf. *supra*, p. 597).

We have seen (p. 612) that tumours and other local organic diseases of the brain frequently give rise to fits which are unattended by loss of consciousness, and consist mainly of convulsive movements, perhaps limited to certain parts. These have been distinguished as Jacksonian convulsions, after Dr Hughlings Jackson (pp. 613, 616). It might be expected that similar fits would sometimes occur in genuine epilepsy. All observers, however, are agreed that this is exceedingly rare. Two instances are recorded, one by Trousseau, the other by Nothnagel. The former occurred in a young man aged eighteen, who was liable to convulsions of the facial muscles, affecting only the left side, and not accompanied by loss of consciousness nor by any other epileptic phenomena. But the clinical history was that the disease had first set in six years previously with violent fits of the *haut mal*, and that these had gradually become milder and passed into those of the *petit mal*, which presumably occurred alternately with the attacks of mere partial clonic spasm. Nothnagel's case was in a boy of sixteen. Dr Reynolds, who gives to this form of the disease the appropriate name of "abortive epilepsy," furnishes a list of references to various writers as having described it. But after looking up most of them we are not sure that these writers took care to exclude cases of cerebral tumour and the like. However this may be, exceptions are very rare to the rule, that whenever attacks of clonic spasm recur paroxysmally without loss of consciousness there is local organic disease of the brain—the disease is symptomatic eclampsia, not idiopathic epilepsy.

Recurrence.—The frequency with which the attacks of epilepsy return varies greatly in different cases. A patient may have one fit without ever having a second; or after an interval of two or three years he may be again attacked. In some cases the paroxysms return once, or twice, or three times a year; in other cases more or less regularly once a month. In women they are, on the whole, more apt to occur at the catamenial periods than at other times. But Dr Reynolds says that monthly recurrence is actually more common in the male than in the female sex; and it is very rare indeed for a woman to be liable to epileptic fits only during menstruation. More frequently the interval at which the attacks recur is less than a month. Lastly, there may be one or more paroxysms every day. It is common for two, three, or more fits to occur on the same day or within two or three days, and then for the patient to be free from them for several weeks. They are then said to recur in *series*. When they return with great frequency during a lengthened period, they almost always belong to the minor form of the disease.

There is, however, a special modification of the disease in which the fits follow one another in rapid succession, so that before the patient has recovered completely from one of them another comes upon him. This has been called by French physicians *état de mal épileptique*, and in England *status epilepticus*. When it is at its height the convulsions follow one another with extraordinary rapidity. Sir Crichton Browne in describing such cases says that the limbs are scarcely laid to rest after one fit before they are tossed and contorted by another, and even in the intervals there are frequent

muscular twitchings. The patient lies perfectly unconscious; his heart beats rapidly and tumultuously; his respiration may either be quick and shallow or slow and laboured. His features are swollen and livid, and his lips purple. His body is bathed in profuse perspiration, and the temperature is raised to 105°, or even higher still. Dr Merson found it in one case 107·8°. This condition often terminates fatally; indeed, it is one of the chief ways in which epileptic patients die. Charcot observes that in such cases bedsores over the sacrum form rapidly. He also mentions that a temperature of 105·8° is sometimes reached without death ensuing.

Complications and sequelæ.—Certain occasional results of an epileptic fit have yet to be described. One is a loss of muscular power in one arm, or in both the arm and leg on one side, generally that side which was the more convulsed. Dr Todd described this under the name of "epileptic hemiplegia;" it may either pass off in a few hours or last several days. One must not forget that diminished mobility of the arm after a fit may be due to a very different cause, namely, to dislocation of the shoulder, produced sometimes by muscular spasm, sometimes by the patient having struck that part in falling.*

At one time a woman who was liable to epileptic fits used frequently to come to the hospital to have her shoulder set. In her case the fact that the same dislocation occurred again and again showed that spasmodic contraction of the muscles was its cause. Still more serious injuries sometimes arise during a paroxysm. The skull may be fractured by the patient dropping down on the pavement; or he may be severely burnt by falling against the bars of the grate; or he may be run over in the street. Persons who are liable to epilepsy cannot be too closely looked after.

Delirium has not hitherto been mentioned as accompanying epileptic fits, but in some cases it is one of the most important features. Indeed, in a person subject to the disease, the attack may be wholly replaced by one of paroxysmal mania (p. 773). Again, the epileptic character may be so far maintained that the patient falls down, but quickly gets up again and attacks those about him with the utmost violence. An instance of this is recorded by Trousseau, who remarks that if there had been no witnesses of the commencement of the attack, the patient would have been liable to a criminal prosecution, since he not only assaulted the passers by in the street, but spat at the soldiers who held him. In other cases the epileptic stupor is succeeded by maniacal delirium, during which suicide may be committed, or murder. Still more frequently a fit is followed by loss of memory, incoherence of ideas, and perversion of intellect, which may last several days. It is not surprising, therefore, that when the paroxysms recur very frequently and at short intervals the mental powers become permanently impaired. Patients who have been long subject to epilepsy acquire a peculiar dull, heavy aspect; and this, with their widely dilated pupils, often enables one to recognise them at the first glance. They are apt to be exceedingly irritable, morose, and gloomy. Sometimes the temper is worse immediately before the epileptic attacks; when a fit occurs it seems to afford temporary relief to the brain, and the patient afterwards feels lighter and more cheerful than for a long time before.

* I myself once nearly overlooked this accident. A patient came with her arm hanging helpless. I was pointing out to the students that a transient paralysis often follows an epileptic attack, when I happened to notice that touching the limb gave pain. I grasped the deltoid muscle, and found that the head of the humerus was out of place.—C. H. F.

Impairment of the intellect is by no means confined to patients who have already suffered for a long time from epilepsy. In children a series of fits, continued for a few successive hours, often produces a permanent state of imbecility, or of mania. A considerable proportion of those who are admitted into asylums for idiots are children who were born with full powers of intelligence, and learned to talk as soon as others; but, having been attacked by epilepsy when perhaps four or five years old, they have since lost sense and intellect, have become dirty in their habits, violent in temper, and unable to recognise their parents. Such cases are frequently brought to our out-patient rooms.

In adults, on the other hand, permanent impairment of intelligence occurs only when epilepsy has been of long standing. Indeed, it is believed that some individuals retain their full vigour of mind after having been liable to fits for years. Julius Cæsar, Mahomet, Petrarch, Peter the Great, and Napoleon are commonly cited as illustrations of the fact that the repeated occurrence of epileptic attacks does not always injure the intellectual powers; but in each of these cases the fits were only occasional, and the evidence of their nature is far from complete. The records of every lunatic asylum afford abundant illustrations that dementia may ultimately overtake those who have been long epileptic before the mind gave way. The severity of the individual attacks has less influence in bringing about such a result than the frequency of their occurrence. Esquirol long ago pointed out that dementia more often occurs in persons who are liable to the *petit mal* than in those who suffer from *le haut mal*.

Pathology.—With regard to the pathology of epilepsy much uncertainty of opinion still prevails. As soon as an attempt was made to distinguish the functions of different parts of the nervous centres it was suggested that in a fit there was a torpor of the brain, associated with excitement of the spinal cord. But the regular order in which one paroxysm succeeds another is inexplicable under such a simple hypothesis; and with the advance of physiology the theory arose that the disease might have its seat in some particular part of the brain as the starting-point of the attacks, or the "epileptic centre." Sir William Gull used to speak of epilepsy as a "function;" and by this he meant that the orderly development of the various symptoms which constitute the seizure must depend upon structural nervous arrangements, like those involved in the more complicated physiological actions. Van der Kolk thought the medulla oblongata was the seat of epilepsy; and recent writers, including Reynolds and Nothnagel, have expressed a similar opinion, but include in the area of disturbance the pons Varolii, or the cervical part of the cord.

We must, however, either confine the supposed "epileptic centre" within very narrow limits, or else include in it the entire length of the spinal cord. We cannot imagine that spasmodic movements of the eyes or of the face bear to such a centre any closer relation than do those of the upper or even of the lower limbs. And if we once give up the idea of fixing the seat of the disease in a definite spot within the medulla oblongata, a little consideration will lead us to include in the affected area the mass of the cerebral hemispheres. There is no other way in which we can so simply explain the facts that consciousness is suspended, and that delirium and excitement are often present. Dr Wilks has always strongly expressed the opinion that epilepsy is an affection of the whole of the brain.

The views entertained by Dr Hughlings Jackson are widely different.

This observer has studied with the greatest care those epileptiform and other convulsions which are caused by local diseases, such as tumours of the surface of the brain. He has laid great stress on the fact that whereas a "destroying lesion," affecting a particular convolution, is capable of causing paralysis, a "discharging lesion" of the same part gives rise to convulsions, which may implicate the opposite face, arm, and leg in a definite order. He supposes that in particular convolutions movements are "represented," which involve the action of many different muscles.

In 1873 Dr Ferrier, following Fritsch and Hitzig, performed a series of experiments on the lower animals, with the express object of throwing light on Dr Jackson's theories of epilepsy (*v. supra*, pp. 615, *et seq.*).

Apart from these experimental results, it would seem, from clinical observations, that when convulsions are set up by local disease of the surface of the brain, the fact that certain parts are especially implicated in the spasms may sometimes enable us to indicate the seat of the lesion. But it is another question whether a similar conclusion is warranted when there is no other evidence of local disease of the brain.

It must also be borne in mind that the spasmodic movements produced by disease—such as are observed in a convulsive attack of whatever kind—are very different in character from the slow and orderly actions to which galvanic stimulation of the brain gave rise in Dr Ferrier's experiments. It is true that spasmodic contractions, and even complete epileptiform fits, were often observed; but these received a separate explanation, as will presently appear. The cases to which reference is now made are those in which, for example, a cat raised the shoulder and adducted the fore-paw, as if to strike; or a rabbit munched with its lips and jaws. In an epileptic fit the affected part is violently jerked backwards and forwards, in a way altogether different from what occurs in its natural movements; and surely this suggests that the convulsive movements do not depend merely upon "discharge" of the cortical centres, but are the results of impressions transmitted thence to the corpus striatum, or to some lower plane of the cerebro-spinal centres.

The case is far stronger when, instead of localised spasms, a complete epileptic paroxysm occurs, in which all parts of the body are convulsed, and consciousness is for the time suspended.

Dr Ferrier has discussed this question in his treatise on 'The Functions of the Brain.' His theory is that in the cortex of the brain there are individual centres for each separate muscular action involved in the epileptic convulsion, that they are related to each other in a constant and definite order, and that the attack is due to the discharge of these centres in a tolerably uniform sequence. Much, he says, depends on the primary source of the irritation, but adds that from whatever part of the hemisphere this proceeds, whether from a motor centre, or from the sensory areas towards the back of the brain, the order most commonly observed is that the centres discharge from before backwards, beginning with those of the head and eyes, and ending with those of the leg. He goes on to say that epileptic convulsions can be produced with as great readiness by application of the irritation to the sensory areas as to the motor centres themselves; and that it is doubtful whether consciousness becomes lost when the motor centres of the brain are alone implicated.

These statements of Dr Ferrier seem to deprive Dr Jackson's views, in their most special form, of the support gained from experiment. But Dr

Ferrier's own hypothesis appears less probable than the older opinion that, even when irritation of the surface of the brain causes an epileptic fit, the actual motor impulses start from the basal ganglia or from centres still lower, in the pons, the bulb, or the cord. Surely the orderly development of the phenomena of the paroxysms is more easily explained in this way.

Again, it is well known that there are cases in which epileptic fits are set up by irritation of spinal nerves—by diseased teeth, or (as in Brown-Séquard's experiments) by pulling the hairs of a guinea-pig, when the spinal cord has previously been injured (p. 761). All such cases of reflex eclampsia are much more easily explained on the view that the parts which are the seat of "discharge" are the lower centres, than on the theory that they are the highest centres of all, in the cerebral cortex.*

At the present time a view is widely prevalent, according to which all but the initial phenomena of an epileptic attack result from vaso-motor disturbance. It is supposed that the cerebral arteries undergo spasmodic contraction, and that the consequent anæmia of the brain causes the patient to fall down insensible. It is well known that the face commonly turns pale at the commencement of a seizure. There is ophthalmoscopic evidence that the retina, which derives its blood supply directly from the internal carotid artery, also becomes anæmic. Dr Jackson and Dr Charles Aldridge have proved that the optic disc is pale or even white, and that the arteries which traverse it are much diminished in size. It is to be noted, however, that on the single occasion on which the ophthalmoscope has been used before the clonic convulsions ceased, the disc was at first pink, so as to be undistinguishable from the surrounding choroid; and that it only afterwards became white, and then slowly.

But the most substantial support of the notion that the brain is essentially anæmic during an attack of epilepsy was afforded by the well-known essay of Kussmaul and Tenner. It had before been known that both in animals and in man loss of blood was followed by convulsions. These observers showed that the like result could be brought about by ligature or compression of the four great arteries supplying the encephalon. In reality, however, their experiments only proved that a deficient supply of blood to the brain might be one cause of attacks of an epileptiform kind. They themselves pointed out that ligature of the trachea, rendering the arterial blood rapidly venous, had the same effect; and in either case they referred the convulsions to sudden interruption of the nutrition of the brain. Their theory evidently does not in any way confirm the more modern opinion, that, when an epileptic fit has commenced in the bulb, the patient becomes unconscious as the result of some reflected influence upon the cerebral arteries, which renders the brain anæmic.

After all, the feature of epilepsy most difficult of explanation is the tendency of the fits to recur at more or less definite intervals; and no way of accounting for this seems to be so satisfactory as to refer it to a gradual accumulation of energy in the nervous centres, which is dissipated during the attacks. As van der Kolk points out, it often happens that after a severe fit an epileptic patient remains free longer than usual; but if

* A further argument may be found in the analogy of another paroxysmal neurosis. A tumour in the brain may excite repeated attacks of migraine. One certainly cannot imagine that these are due to "discharge" of the part which is immediately affected by the tumour; they must be due to an influence transmitted downwards to the thalamus or to other sensory ganglia.—C. H. F.

he should have only a slight attack, he soon afterwards has another, perhaps on the following day. Again, in some cases each fit is preceded by a gradually increasing irritability of temper and restlessness, which disappear or are notably diminished after it has taken place. Other patients, as Trousseau remarks, become gay, loquacious, and excited for some hours before an attack; and yet others complain of failure of memory, of torpor, and of physical and mental prostration. Nothnagel mentions the case of a lady, generally a light sleeper, who always knew that she was about to have a paroxysm when she happened to sleep more heavily and longer than usual; nevertheless she would wake up feeling quite well, and would not be attacked until later on in the day.

We are thus brought to regard epilepsy as essentially a paroxysmal neurosis, recurring at more or less regular intervals. In all probability the alterations in the blood supply to the brain, which undoubtedly occur during the epileptic attack, are accidental concomitants rather than essential to the development of any of its symptoms. This view is not inconsistent with the fact that the inhalation of nitrite of amyl is sometimes of service in the treatment of the disease; for when there is an aura the attack can sometimes be overcome by a decided impression on the part to which the aura is referred, and the inhalation may fairly be supposed to act in a similar way, and to cut short the paroxysm by arresting one of its phenomena. Moreover, venesection is sometimes useful, apparently under the same circumstances as those in which the nitrite does good. Yet they must produce contrary effects.

To sum up, then, we must at present be content to adopt the language of some modern writers, and say that epilepsy is "dependent upon an unstable condition of the nerve-tissue in some portion of the nervous system, permitting occasional discharges." This, in reality, is not stating more than that the disease is a "nerve-storm." Just as in migraine, teichopsia may be followed in succession by numbness in the fingers, by headache, by vomiting, and by sleep, so in epilepsy tonic spasms give place to clonic convulsions, and these, again, to stupor or coma. It appears more satisfactory to refer this sequence of phenomena to the gradual extension of some morbid condition from one part of the nervous centres to another, than to ascribe it to modifications in the blood supply.

This account of the pathology of epilepsy can hardly be regarded as complete without some reference to the remarkable experiments of Brown-Séquard, who found that in guinea-pigs and some other animals section of the spinal cord, or even of one or both sciatic nerves, was followed after some weeks by well-marked epileptiform fits, which returned again and again, and could at any time be excited by slight irritation of the cheek (as, for instance, by gently pulling the whisker) or of the side of the neck. The exact bearing of these interesting observations, however, seems to be doubtful, so far as concerns epilepsy in the human subject. They do not afford any support to the idea that the epileptic aura really starts from a distal part of the body and travels along sensory nerves, setting up the paroxysm when it reaches the encephalon. There is every reason to believe that the aura is itself part of the attack, and due to a change in some region of the brain which has close connections with the roots of certain cutaneous nerves; the disturbance is accordingly referred to the peripheral distribution of these nerves.

Ætiology.—In passing on to consider the causes of epilepsy, we have in

the first place to consider *hereditary predisposition*. Dr Reynolds made inquiries which led him to the conclusion that in 12 per cent. of his epileptic patients the same disease had occurred in other members of their families. But this was not all. For in a much larger number of cases other affections of the nervous system could be traced in persons derived from the same stock as the patient. Sometimes it was migraine; sometimes insanity, hysteria, hypochondriasis, or mere nervousness. Thus in a family in whom nervous disorders prevail, one child may be epileptic, another insane or idiotic, and a third hysterical. Several independent observers state the proportion of hereditary nervous influence at about one third of the total cases of epilepsy. Drunken habits in parents are also believed to predispose to epilepsy in their offspring; but the inclination to intemperance may itself be a sign of a neurotic tendency.

There is no reason to suppose that tubercle, rickets, or general malnutrition is concerned in the causation of epilepsy. Nor does intermarriage of blood relations tend to cause this disease in the offspring, provided that neither parent is predisposed to it.

As to predisposition of *sex* and *age*, epilepsy appears to affect males and females in about equal proportions, notwithstanding the remark of Celsus, "*sæpius viros quam fœminas occupat*," and the opposite result of some modern statistics. Dr Reynolds makes some sagacious remarks ('System,' vol. ii, p. 295) on the fallacies of statistics in this respect.

The *time of life* at which epilepsy begins in the great majority of cases is between the tenth and the twentieth years. Dr Reynolds found that in 106 out of 172 cases the first fit occurred between these limits of age, and in most it was within the still narrower period of from thirteen to seventeen years. The more marked the inherited predisposition, the earlier is the average age at which the disease develops itself, and it appears in girls sooner than in boys. Apparently the development and commencing activity of the sexual organs are in some way concerned in the causation of the disease. It has been said that in women the time at which the menses cease to appear is again apt to be attended with the development of epilepsy, but Nothnagel says that this is not the case. According to Dr Reynolds, the period between twenty-five and thirty-five years of age is one at which there is a comparative immunity from first attacks; but they often occur in persons about forty. Exceptional instances are recorded of epilepsy beginning at an advanced age; one, for example, by Trousseau, at about sixty-nine.

In other cases epilepsy is not inherited, it is an acquired condition.

Habits of *intemperance*, *sexual excesses*, and particularly the practice of masturbation are believed to be directly concerned in bringing it about. Indeed, both a first fit and succeeding ones have in some individuals occurred only when they were actually intoxicated, and in others only during coitus. With regard to masturbation, all modern writers speak very guardedly, although there is no doubt that this degrading habit has a most depressing effect upon the health of immature youths, and is capable of causing serious nervous symptoms.* That epilepsy may be produced by alcoholic poisoning, and also by plumbism, there is no doubt.

* I do not believe in the existence of any unfelt irritation starting from the genital organs of modest young women, and giving rise to epilepsy or any similar disease. And I regard as an abomination the operation of clitoridectomy, which was some years ago practised upon a theory of that kind.—C. H. F.

Prolonged anxiety of mind, grief, and destitution have been supposed to lead to epilepsy, but on no sure grounds.

With regard to definite *exciting causes*, there is much difficulty in eliciting the real facts. On the one hand, the parents of children affected with epilepsy are much disposed to conceal a family tendency to that or any other serious disease; and patients themselves are apt to be unacquainted with the real state of health of relatives older than themselves. On the other hand, there is a strong tendency to attribute the disease (and many others, as phthisis) to any accidental circumstance which can by possibility be brought into relation with the first attack. Trousseau says that when a fright was assigned as the cause of epilepsy, he often found on inquiry that it had really occurred months or even years before the fits began, or that it was trifling in character. He himself, however, relates a case in which it appeared clear that the original cause of epilepsy was the terror caused by the sight of a quarrel between two men, one of whom was wounded and fell down dead. In that instance the first attack of *petit mal* occurred within a few days, and subsequently the *haut mal* developed itself.

We have next a very important point to determine, namely, why the first fit should be followed by others. For in some cases the disease has followed attacks which are commonly regarded as accidental in origin.

Thus Dr Hughlings Jackson mentions a case in which a convulsive fit at the onset of scarlet fever proved to be the forerunner of habitual epilepsy. Again, it is said that the simulation of the disease by impostors has ended in their becoming really subject to it; and, if true, this is a still stronger fact in the same direction. Brown-Séquard found that the guinea-pigs in which he artificially set up epilepsy transmitted it to their offspring as an idiopathic disease.

On the other hand, some very remarkable cases are recorded which show that even when epileptiform fits have occurred at intervals for a very long period, as the result of irritation of the nervous centres by some cause acting on a distant part, the liability to their recurrence may cease when the cause in question is removed.

Thus Mr Tomes relates the case of a farm labourer suffering from epilepsy, whose mouth was examined, and the molar *teeth* of the lower jaw were found to be decayed, the fangs of some of them alone remaining. Although he had been treated for the fits during six weeks and complained of no pain, these teeth were removed, and were found to be enlarged from exostosis. During the eighteen months that followed he had not a single fit, although for many weeks before the operation he had had two or three daily. Another case, recorded by Dr Ramskill, is that of a boy who for eighteen months had had epileptic fits, and in whom it was noticed that before the fits he used to rub his left cheek on account of an indefinite uneasiness, not amounting to pain. On examination a molar tooth considerably decayed was found; this was removed, and from that time the boy did not have another fit, although he remained under observation for four months. It must be added, however, that during that period belladonna was administered. A most extraordinary case is one related by Trousseau, of a young clerk, who for several years had been subject to monthly attacks of epilepsy; remedies had been tried in vain at the Hôtel Dieu, when Dr Foville suggested the extraction of some carious teeth which ached constantly. The suggestion was acted on, and from that day the fits disappeared.

Trousseau also relates the case of a man, aged forty, who on several occasions, at very short intervals, was seized with violent epileptic attacks. Dr Monnier found that he had been passing fragments of *tænia*, and gave him large doses of castor oil; a whole tapeworm came away, and from that time the convulsive fits ceased.

Again, an *injury* to the head may be the starting-point of habitual epilepsy. Nothnagel gives the case of a boy who when eight years old fell from a height of twelve feet upon his head. He was stunned for a quarter of an hour, and ten minutes after recovering consciousness he had a characteristic epileptiform fit. There was a slight scalp wound, which healed in a few days. After six weeks he had a second attack, and from that time they recurred at periods which became shorter until he had them at intervals of from four to twelve days. He was twenty-one years old at the time when Nothnagel wrote, and his intellect and memory were already somewhat impaired. A slight scar remained, but this was not painful nor adherent. Nothnagel seems not to have thought that surgical interference would have done any good; and perhaps he was right. But in the 'Lancet' for 1873 two cases will be found recorded, in each of which a piece of the skull was removed by the trephine on account of epileptic fits following an injury to the head. Both of them occurred at Guy's Hospital, the one under Mr Cooper Forster, the other under Mr Bryant. The former patient had received a blow on the head four months before his admission; it left a slight swelling, from which a little pus exuded when it was incised. His first fit occurred the day before he came into the hospital. But a week later he was having four or five fits every hour, and his temperature was 103°. The skull was then trephined, and the piece of bone which was removed was very dense, three eighths of an inch thick in one place, and rough on the outer surface. A fortnight afterwards he could walk the length of the ward, and he never had another fit—at least until the time when the report of the case ceases, which was two months from the date of the operation. In Mr Bryant's case the accident had occurred five years before, and attacks of the *petit mal* had occurred at intervals of about a week during the whole period. The cicatrix was still tender, and occasionally painful. Internal treatment having been tried without any good result, the trephine was applied, and a piece of thickened bone removed. The fits at once became less frequent, and seemed to occur only when he was depressed from want of food in his miserable home, or when he was exhausted by diarrhœa. The same medicines which he had before taken with no benefit were resumed, and after a time he became able to earn his living. When the case was reported sixteen months later, he seemed to be permanently cured.

Relation to other convulsive fits.—One point in favour of a real distinction between true epilepsy and symptomatic eclampsia is the observation of Dr Tyler Smith that puerperal convulsions are by no means of frequent occurrence in women who are habitually subject to epileptic fits. But it is clear from the foregoing paragraphs that there may in practice be great difficulty in applying the distinction in question. Another instance of the same difficulty is afforded by infantile convulsions. On the one hand, it is said that persons subject to epilepsy in adult life are often found on inquiry to have had fits in early childhood. Nothnagel expressly states that this is often the case with children born of epileptic parents, and with those who in later years themselves become epileptic. But, as Dr Jackson points out, there are at present no facts to show what is the proportion of

those who having had infantile convulsions afterwards escape epilepsy; it can hardly be doubted that they form the immense majority. The fits of infants were formerly attributed to irritation of the nervous centres from teething or disorder of the alimentary canal. But the more closely such supposed causes are inquired into the less clear does their relation to the convulsive attacks appear to be. The tendency of modern observation is to associate infantile convulsions and laryngismus stridulus with rickets. Whatever part in their causation one may assign to external sources of irritation, it is certain that another very important part is due to inherited or acquired conditions of the nervous centres, disposing them to convulsive discharge. It may well be that in infancy the brain yields to influences which in after life it successfully resists. The higher centres of the cortex have not yet acquired inhibitory or restraining influence over the lower excito-motor mechanisms of the basal ganglia and the cord. It would be a serious error to say that the occurrence of fits in childhood involved danger of epilepsy in adult life: yet it seems clear that no absolute line of distinction between them can be drawn; nor, in general, between habitually recurrent epilepsy and the various forms of eclampsia, or of epileptiform fits due to external irritation.

The difficulty is evaded if we regard all these affections as members of the same group of paroxysmal neuroses.

Anatomy.—The only morbid changes which are to be found in the brain in epileptic patients must be regarded as *effects*, and not as *causes* of the fits. Perhaps the most important are dilatations of the capillary blood-vessels in the bulb. These were first described by van der Kolk, who maintained that there was a definite relation between their seat and the symptoms observed in the paroxysms, the nucleus of the hypoglossal nerve and the olive (*corpus olivare*) presenting dilated vessels when the tongue had habitually been bitten; whereas in cases in which the tongue escaped he found them chiefly in the nucleus of the vagus. He also described an albuminous exudation into the bulb, causing at first induration of its substance, but afterwards fatty degeneration and softening. Similar conditions have been described in cases of hydrophobia, of tetanus, and of chorea.

The skull is often exceedingly thick and dense in those who have long suffered from epilepsy, the membranes are opaque, and the brain generally is indurated; but these changes seem to bear a closer relation to the impairment of intellect which is so generally present in cases of long standing than to the primary paroxysmal attacks.

Diagnosis.—This involves several different questions, some of which have already been dealt with, or will be considered in other chapters. For example, one may have to distinguish an attack of minor epilepsy from one of *cardiac syncope*, and an attack of major epilepsy from one of *hysteria*.

(*a*) When a person is in a fit, which, if really epileptic, would belong to the major form, we have often first to ask whether it is possible that he is *malingering*. In the first place an impostor is likely to choose for his fits a frequented spot, where he is sure to be seen. When he throws himself upon the ground it is in such a way as not to hurt himself; he may even put out his hands to break his fall. He probably overacts his part, crying out many times instead of only once, throwing his limbs violently about, and making the attack last much longer than a genuine paroxysm of epilepsy. There is, of course, no pallor of his face at the com-

mencement; his skin, instead of being cold, is warm and covered with sweat; his pulse, even if quickened, does not become irregular; his pupils are not dilated, nor insensible to light. He does not keep his eyes wide open, nor are the eyeballs distorted; generally he only separates the lids a little from time to time, so as to watch the bystanders. If an attempt should be made to raise the upper eyelid he resists it, and instead of his conjunctiva being insensible, the slightest contact excites forcible contraction of the orbicularis muscle. On the other hand, he may readily allow the thumbs to be drawn away from the palms, and afterwards close them again. But, according to Dr Marc, in a person really attacked by epilepsy the thumbs require force to loose them; and, when once extended, they remain so until the end of the attack, or at least until a fresh convulsion begins. Again, in a simulated fit the tongue is seldom or never bitten, and there is no foam about the mouth—unless, indeed, this is imitated by a piece of soap in the cheek. The muscular strength of a malingerer is not increased. If a little snuff be blown into his nostrils he cannot help sneezing; in a real fit no such effect is produced. Another test is the absence of sensibility to pain: a test commonly adopted by policemen and others is to press the thumb-nail forcibly beneath that of the person supposed to be in a fit. As already mentioned, there is reason to believe that repeated attempts to feign epilepsy have sometimes ended in the development of a genuine attack.

An educated medical man would naturally succeed in imitating a fit better than one who has no professional knowledge. Trousseau relates that Esquirol, who did not believe that an attack could be simulated so as to deceive, was once talking this very matter over with him and with Calmeil at the asylum at Charenton, when the latter fell on the floor in violent convulsions. Esquirol examined him for a moment, and then said, "Poor fellow, he is epileptic!" upon which Calmeil got up and asked him whether he still retained his opinion.

(*b*) Assuming our patient's attacks to be genuine, one has next to consider whether they are really epileptic or epileptiform. This question is often settled by the clinical history; the case may, perhaps, be of many years' standing, and the fits may have gradually developed from the minor into the major form. But one must bear in mind that attacks may recur at intervals for a great length of time, and present all the characters of idiopathic epilepsy, and yet be symptomatic. Trousseau's case has been already mentioned, of the clerk who had been liable to epileptiform seizures for several years, at monthly intervals, and in whom they ceased when some carious teeth were removed. The same writer relates the case of a lady, aged seventy-one, who for thirty-one years had been subject to attacks recurring with daily increasing frequency, so that she at length had as many as twenty-one in the twenty-four hours. Her forehead and nose presented characteristic signs of former syphilitic disease; and the administration of mercury and iodide of potassium checked the fits.

(*c*) Generally, however, the question of syphilis need hardly be entertained unless the fits are comparatively of recent origin; and the same may be said of Bright's disease, lead-poisoning, chronic alcoholism, and the various organic affections of the nervous centres. The diagnosis between these diseases and true epilepsy must depend mainly upon the presence or absence of the other symptoms which severally characterise them, and upon the condition of the patient between the attacks.

Prognosis.—If we separate the "true" idiopathic disease from sympto-

matic eclampsia due to injury, tumours or other "gross" lesions of the brain, the epileptiform convulsions of uræmia and of the puerperal state, hystero-epilepsy and infantile convulsions—we shall find that epilepsy is no less grave in its prognosis than alarming in its symptoms; and although by treatment we can greatly reduce the number and severity of the attacks, it is only in exceptional cases that we can cure it.

If epilepsy begins in childhood there is good hope that it will disappear about puberty. Eclampsia occurring for the first time after fifty is usually symptomatic.

The frequency of the fits is of worse prognosis than their severity. True *petit mal* commonly ends in *grand mal*.

Hereditary epilepsy is, as a rule, the most difficult to cure.

When no improvement takes place under treatment, and no cause or occasion of the attacks can be discovered and removed, the natural progress of the disease is towards mental imbecility.

Treatment.—In the treatment of epilepsy two things have to be considered: (1) the management of the attacks themselves; and (2) that of the intervening periods, with a view to prevent their recurrence.

(1) So far as concerns *the paroxysm*, the most important point is to ascertain whether the patient has any warning of its approach. If there should be a distinct aura, starting, perhaps, from the hand or foot, one can often, by compressing the limb above, arrest the fit after it has commenced. Some years ago there was, in the Evelina Hospital, a girl who constantly wore round her wrist a piece of cord; this was pulled tight as soon as she felt the sensation which indicated that she was about to have an attack, and not a single one developed itself during several weeks; after a time bromide of potassium was administered, and the aura then ceased to recur. Many instances of a similar kind have been placed on record by different observers. Dr Bazire mentions the case of a woman whose fits were always preceded by spasmodic closure of the left hand; by forcibly extending the fingers, and keeping them open, an impending attack could be warded off. A patient of Dr Reynolds' had jerking of the left leg, which was drawn up behind him, when his attack began; it was arrested by extension of the muscles. Another plan which has been recommended consists in cauterising the surface from which the aura proceeds.

Even when an epileptic fit is not ushered in by any symptoms beyond pallor of the countenance and tonic spasms, it would appear that the prompt inhalation of nitrite of amyl is sometimes capable of arresting it. Sir Crichton Browne has related some instances of this. One is that of a man who started up suddenly in bed, with his eyes fixed and his head turned to one side; these symptoms were known to indicate the approach of an attack; but the nitrite was administered, and the patient at once fell back on his pillow in a half-fainting state, but without the slightest agitation of the muscles. In another case a fit had actually begun in the ordinary way with rigid stretching of the hands by the side, and turning up of the eyeballs, when the nitrite was held to the mouth and nostrils, and in twenty seconds complete recovery had taken place.

After an epileptic attack has fully developed itself, there is evidence that it may still sometimes be cut short by compression of the carotid artery in the neck. This procedure must be supposed to diminish to some extent the blood supply to the brain. It was first suggested by Dr Parry, of Bath, towards the end of the last century. He relates a case in which it proved

successful. A man who had been liable to epilepsy for two years was one day beginning to have a fit; his eyes were assuming a vacant stare, and convulsions were beginning about his throat, when Dr Parry made strong pressure over the right carotid artery; upon this the convulsions ceased, and the attack proceeded no further. He instructed the patient how to compress the vessel, and the latter afterwards assured him that when he had sufficient warning he was often able to prevent the epileptic paroxysm. At Guy's Hospital this practice was adopted by the late Mr Stocker, and sometimes with striking results. But it was most useful in cases with a strong hysterical element. The plan which Mr Stocker used to adopt was to press both thumbs into the neck, one on each side, towards the spine; in doing so he doubtless compressed many other parts beside the carotid arteries, and the pain caused may well be supposed to have been concerned in the rapid restoration of the patient to consciousness, at least when the case was hysterical.

When we are called to a patient in an epileptic seizure we must see that his clothes are loosened, especially about his neck, and we must take precautions to prevent his injuring himself. We may endeavour to keep the tongue from being bitten by putting a piece of india-rubber between the teeth, but this involves the risk of its falling back into the throat and causing suffocation. Epileptics who are liable to attacks in the night should be very careful to remove false teeth from the mouth before going to bed, lest they should become impacted in the pharynx during a paroxysm.

In the *status epilepticus* it would appear that the best remedy is the inhalation of the *nitrite of amyl*. Sir Crichton Browne has recorded ten cases in which he employed it, and eight of them terminated in recovery. The effects of the remedy were of the most striking character. For instance, a man, aged thirty, had from May 6th to the 10th had from twelve to sixteen fits a day; on the 11th he was in a most critical condition; he lay on his back, breathing stertorously, with livid purple features, and streaming with perspiration; the pulse was 140, the temperature 103°. It seemed useless to make trial of the nitrite, but as a forlorn hope he was made to inhale five drops every hour. His breathing at once became less laboured, and he had only three more fits that day, and on the 12th there were gleams of consciousness; the pulse and temperature fell; on the 14th he could answer questions, and by the 17th the fits ceased, and he passed into his usual state of health, and was able to take part in domestic work. Dr Browne adds that he has found no other plan of treatment of nearly the same value in the status epilepticus as inhalation of the nitrite of amyl, although other measures may occasionally be useful.

The withdrawal of a few ounces of blood has sometimes suddenly restored to consciousness patients who were in a state of profound coma. Some years ago a very striking instance of the same kind occurred at Guy's in the practice of Dr Wilks. Perhaps this undoubted benefit of *venesection* in apoplectic epilepsy may explain the reputation of bleeding in cases of cerebral hæmorrhage.

(2) For the *prevention* of epileptic fits in those who are liable to them—in other words, for the cure of the disease epilepsy—the *bromide of potassium* surpasses all other drugs in efficacy. Sir Charles Locock, in 1857, was the first to recommend it, and he spoke of it as being especially serviceable in women in whom the attacks coincided with the menstrual periods. But subsequent observations have shown that there is no such limitation of its curative

power. It is given in doses of from ten to thirty grains three times daily, and it must be continued for months, or even for two or three years. Its effect is sometimes to free the patient for ever from the liability to recurrence of the attacks. In other cases it suspends them for a time, or diminishes their frequency and severity, but when its administration is suspended they soon become as bad as before. In yet other cases it does some good for a time, but seems to lose its power, although the patient may go on taking it without interruption. Lastly, in a very few instances it appears to be altogether useless. No explanation has yet been found for the varying effects of bromide of potassium in different cases.

Most persons can take from ten to twenty grains of bromide of potassium three times daily without suffering any ill effects. But when it is given in larger doses it is apt to cause very striking symptoms after ten days or a fortnight, and the condition so produced has been called *Bromism*. According to Dr Bazire (Syd. Soc. translation of 'Trousseau's Lectures,' vol. i, p. 100) it is characterised by headache, apathy, impairment of the special senses and of common sensations, loss of sexual appetite and vigour, enfeeblement of muscular power in the limbs, tremor of the hands, and impaired action of the heart. A young American lady came under the writer's care, who, after taking bromides for several years to cure epilepsy, had fallen into a dull, stupid, listless condition, sitting for hours without moving, and incapable of joining in society. A very definite symptom of bromism is anæsthesia of the velum palati, uvula, and pharynx, which may be tickled without producing any efforts of deglutition.

Another remarkable effect is the production of a cutaneous eruption. This commonly resembles acne more or less closely; it consists of pustules surrounding hair-follicles, but these are arranged in patches or groups, and dry up into large scabs, beneath which the skin becomes red and thickened. One case of this kind is depicted on the forty-third plate of the Sydenham Society's 'Atlas.' In that instance the scalp and the extensor surfaces of the limbs were especially affected by the eruption, but the face and the legs are more often its principal seat. This unpleasant effect of bromides may be prevented or mitigated by adding arsenic to the medicine.

One is not infrequently consulted by a patient who has just had a first epileptiform attack. The bromide should then be prescribed without delay. The probability of its usefulness may fairly be inferred from its ascertained efficacy in the large proportion of the cases in which its value can be fairly tested. If one were to lay the matter in all its bearings before the patient himself, he would certainly wish to take the medicine regularly for a considerable length of time, even though, in the event of his remaining free from further attacks, it must always remain doubtful whether or not there was a real necessity for treatment.

If the bromide of potassium fails to check the recurrence of attacks of epilepsy, although given in large doses and with the utmost perseverance, we must then have recourse to some other remedy; and perhaps the best is *belladonna*. This was especially recommended by Bretonneau and by Trousseau. At first a quarter of a grain of the extract should be given twice or three times a day; and the dose should be gradually increased. At one time a patient of the author's took two grains three times daily for a great length of time, with marked benefit. Trousseau insists on the necessity that belladonna should be continued for a long period if its value is to be fully tested; a year, he says, is sometimes scarcely sufficient

for the discovery of its influence; and if in the second year there should be some improvement it may be worth while for the patient to go on taking it for three or even four years. He speaks of it as completely curing the disease in some very rare cases; but Dr Reynolds has never known it do more than diminish the frequency of the seizures.

The salts of *zinc* are useful in some cases of epilepsy. Dr Wilks has had under his observation more than one case in which the patient was always better when under their influence. Dr Reynolds speaks favourably of the oxide, but has seen no good result from the sulphate.

The nitrate and the oxide of *silver* have been recommended, but are probably useless. And one must not forget that, taken for a length of time, this drug will stain the skin of a bluish-black colour. It is believed that these preparations may be administered with safety if the course is not allowed to be continued for more than six weeks. Twenty years or more ago an American was to be seen about London who had been castrated and afterwards completely blackened by nitrate of silver in the hope of curing his epilepsy. His skin looked as if it had been polished with black-lead, but the result was negative so far as the disease was concerned.

In some cases the introduction of a *seton* into the nape of the neck has led to the suspension of epileptic fits. A patient of Dr Wilks in Mary Ward, subject to epileptic fits, had a seton put in her neck. The fits ceased entirely. After more than a year the seton was removed and they reappeared. It was again inserted, and again the convulsions ceased.

The application of ice to the spine, as recommended by Dr Chapman, has been fully tried by Dr Reynolds, who reports that it did no good.

Trephining is a very dubious remedy in cases of idiopathic epilepsy, though useful in Jacksonian eclampsia from a cortical lesion.

The food of patients suffering under epilepsy should be digestible, and their meals leisurely and regular. Dr Wilks speaks of having seen cases in which reducing the quantity of meat has been followed by a decline in the number and severity of the fits; but in other instances a generous diet has been advantageous. The writer knew a lady who, by the late Dr Radcliffe's advice, lived on vegetarian diet for some years; and the effect in checking the fits both in frequency and severity was marked. Some definite experiments in regard to the influence of animal food have been made at the West Riding Asylum by Dr Merson, who kept a number of patients for a month on a diet including much meat, and then for the same period on one in which there was none at all; there was no marked difference in the number of fits, but several of the patients were much more dull and languid when taking animal food than when restricted to farinaceous diet.

Both the mind and the body of epileptic patients should be kept in exercise, short of fatigue. The limbs should never be allowed to get cold, particularly at night. Dr Reynolds says that in many cases nocturnal seizures have been prevented by a prop being put under the upper half of the mattress, so as to keep the head and shoulders well raised.

PAROXYSMAL VERTIGO.* — Another affection which may occur in paroxysms is vertigo or giddiness. The term "paroxysmal vertigo" is better than "epileptic vertigo," for the latter has been used as a synonym for the less severe form of epilepsy—the *petit mal*, which is not usually

* Vertigo (*vertere*, to turn) answers to the English words giddiness or swimming of the head.—*Fr.* Vertige.—*Germ.* Schwindel.

attended with giddiness, and it is almost always attended with loss of consciousness (cf. p. 751).

Two forms of paroxysmal vertigo are recognised by systematic writers. In one the patient feels as though he himself were made to turn round and round, or were against his will impelled forwards, or backwards, or to one side. In the other he fancies that objects are revolving round him. In each case he remains perfectly conscious, and all that occurs is duly registered in his memory. If he has had previous attacks, he may be well aware that his sensations are without foundation; yet by the strongest effort of his will he is incapable of overcoming their effect. In a first attack he may be completely deceived. A patient, who happened to be travelling by railway, beheld one side of the carriage suddenly rise four or five feet, and throw him into the opposite corner. He naturally supposed that there was a serious accident; but in reality he had not moved from his seat. Dr Ramskill relates that a patient of his, who was attacked while in the street, felt the pavement uneven, with alternate depressions and elevations over which he seemed to be obliged to lift his feet. At the same time the shop windows seemed to him to be moving forwards, and the passers by to be racing after one another. But he also felt giddy in himself; and as a matter of fact the two forms of vertigo just described cannot be regarded as distinct affections. In most cases both are experienced, either at the same time or successively.

The gait is unsteady or reeling; the patient feels afraid of running against other people or surrounding objects; he catches hold of some support; or he may lose his balance and fall to the ground. Sometimes closing the eyes removes the sensation of vertigo for the time. Nausea commonly accompanies the attacks, or even vomiting.

Paroxysmal vertigo is often connected with impairment of the sense of hearing, the patient being more or less completely deaf on one or both sides, and generally experiencing sensations of buzzing or singing in the ears. In 1861, Ménière recorded in the 'Gazette Médicale' some remarkable instances of this kind; and such cases have been described under the name of Ménière's disease, "auditory," "aural," or *labyrinthine vertigo*; but the prevalent interpretation of their pathology is far from proved.

In the first place, it is certain that affections of the middle, and even of the external ear may give rise to attacks of giddiness, faintness, and sickness. For example, in the 'Archives of Ophthalmology and Otology' for 1871, both Knapp, of New York, and Brunner, of Zürich, mention cases of aural catarrh in which such symptoms appeared; and Toynbee many years ago asserted that cerumen accumulated in the external meatus might by its pressure on the membrana tympani produce similar effects.

In the great majority of cases, however, the more accessible parts of the organ of hearing are free from disease. If the deafness is of one ear, a tuning-fork is not heard on that side, even when placed upon the teeth or upon the top of the head. It is hence inferred that the seat of mischief must be the internal ear.

At this point some very interesting physiological observations appear to find their application. Many years ago Flourens discovered that in pigeons and rabbits section of the semicircular canals causes strange disturbances of equilibrium. More recently Mach, of Vienna, and Crum Brown, of Edinburgh, have shown good evidence that the function of these structures is to

furnish the impressions which form the principal basis of our knowledge as to the relation between our movements and those of surrounding objects. They have even shown what are the several disturbances of equilibrium which irritation or destruction of each canal may be expected to produce. Charcot observed a case of paroxysmal vertigo in which the lesion was chiefly in the left ear, and in which the direction of reeling was principally forwards, but sometimes backwards, while occasionally there was a sense of rotation on a vertical axis, always from left to right. This last would, according to recent writers, be due to irritation of the left horizontal ampulla, while movements forwards and backwards would answer to irritation of the posterior and superior canals respectively. Destruction of the same parts would, however, produce precisely the converse effects, and thus there is no difficulty in accounting for the fact that some patients have shown a tendency to reel towards the side on which they were deaf. In either case the actual movements are supposed to be the reflex results of the impressions conveyed to the co-ordinating centre from the several canals, which under normal conditions balance one another, but which no longer do so when one of them is diseased or injured.

Even when morbid changes in the meatus or tympanum are obviously present, it is commonly supposed that the direct cause of vertigo is disorder of the labyrinth; for pressure upon the fenestra ovalis can easily be conceived to cause increased tension in the semicircular canals. Thus all cases of "auditory vertigo" might come to be regarded as alike examples of Ménière's disease or labyrinthine vertigo.

Ménière himself did not merely wish to draw attention to the fact that vertigo is apt to occur in those who suffer from deafness or from some disease of the internal ear; for this was well known before. What was really new in his paper was that he endeavoured to show that sudden apoplectiform symptoms (including at least a transient loss of consciousness) might occur in a person previously healthy, might be followed by deafness, and that the cause of such attacks might be an affection of the internal ear. He relates several cases of patients who fell down insensible, and who, when they recovered, were found to be deaf; and a similar instance has been recently recorded by Knapp.

The only one of Ménière's cases in which a *post-mortem* examination was made is the tenth and last of his series. A young woman, while menstruating, undertook a night journey outside a coach. She suddenly became completely deaf, and was admitted into Chomel's wards. The principal symptoms were constant vertigo and vomiting. She died on the fifth day. At the autopsy no disease could be discovered in the nervous centres; but the semicircular canals in each ear contained a reddish plastic substance. Surely this observation is very inconclusive. Cases in which an autopsy fails to reveal a satisfactory explanation for cerebral symptoms present during life are, after all, not very rare; and it seems rash to assume that the state of the labyrinths was the real cause of the fatal illness in Chomel's patient. Moreover, as Brunner points out, even if full value were allowed to the case in question, one could hardly take it as demonstrating the nature of those other cases in which cerebral symptoms come on suddenly and rapidly pass off. In these it has been supposed by Knapp that hæmorrhage takes place into the semicircular canals. But since the deafness is often simultaneous in the two ears, the blood must be effused on both sides at or about the same time, and this makes the explanation very improbable.

It is true that hæmorrhage into both retinæ occurs in cases of Bright's disease; but surely not so as to cause sudden and total blindness.*

A different view has been suggested by Dr Wilks; namely, that when there is no affection of the meatus or tympanum, the deafness and the cerebral symptoms are both in some cases due to changes in the nervous centres. It is evident that such an explanation is particularly applicable to cases of Ménière's disease in the stricter sense of that term; the sudden loss of hearing in both ears may fairly be attributed to an affection of the auditory centre; and the giddiness to a similar affection of the centre for equilibrium, which is probably adjacent, since its most important afferent nerves are those which come from the semicircular canals. Whatever peculiarities in the direction of the vertiginous tendencies may be observed, such as have been supposed to depend upon affections of particular ampullæ, they can all be referred to corresponding changes in the centre, for in this the functions of each canal must be fully represented. The analogy of the other paroxysmal neuroses strongly supports Dr Wilks's view. Impairment of sight is a frequent symptom of migraine, and it is certainly due to an affection of the brain and not of the eyes. Indeed, "cloudiness before the eyes" and "obscuration of the visual field" are mentioned as having been present with the vertigo in some of Ménière's and Knapp's cases; and it may be that in these instances the attacks presented a combination of the two neuroses, the nerve-storm spreading beyond its usual limits and encroaching upon the area concerned in migraine. So also in the "apoplectiform" cases described by Ménière, we may account for the loss of consciousness by supposing that the disturbance spread over the hemispheres, as it probably does in epilepsy.

Another strong argument in favour of Dr Wilks's view is afforded by the fact that bromide of potassium may remove both the giddiness and the loss of hearing at the same time; and Mr Hinton recorded under the name of Ménière's disease a case in which paroxysmal vertigo and sickness had been associated with only transient deafness, and in which all these symptoms together were brought back by the administration of quinine.

Knapp has observed that in certain cases the impairment of hearing is particularly marked for certain musical tones, those of the middle octaves being distinctly perceived, while those of the lower, and still more those of the higher octaves are heard very imperfectly. He regards this as a proof that the seat of the affection is in the labyrinth; but the force of the argument is not obvious. Much more weight must be allowed to an observation of Charcot's, that some patients experience sensations of vertigo and buzzing in the ears only so long as the deafness is partial, and lose these symptoms as soon as it becomes complete. But even if we should have to admit that in these instances the internal ear is really the part primarily affected, it would by no means follow that the same thing is true of the "apoplectiform" cases, nor that the vertigo is anything but a neurosis. Why may not the same symptoms be produced in many different ways, and yet be always themselves the immediate result of one particular kind of nervous disturbance? Epilepsy and migraine may be excited by a variety of causes, and so may paroxysmal vertigo.

The late Mr Hinton published nine cases of vertigo, mostly paroxysmal, and associated with deafness, tinnitus, and nausea or vomiting, in the 'Guy's

* The writer once saw retinal hæmorrhage in the course of chronic Bright's disease cause sudden and total blindness; but in that patient the other retina had been long affected without his knowledge.

Hospital Reports' for 1873 (vol. xviii, p. 193). In some of these the hearing was affected on both sides, and in two (Cases 3 and 9) the perception of certain musical sounds was definitely impaired.

A classical instance of vertigo, nausea, deafness and pains in the head, coming on as a paroxysmal disease early in life and persisting until old age and senile imbecility, is that of Dean Swift. Dr Legg and Dr Bucknill have argued in favour of its being a typical case of Ménière's disease; but we have, of course, no knowledge of the condition of the labyrinth. Swift's account of the origin of his attacks in a fit of indigestion while he was living with Sir William Temple would point to *vertigo a stomacho læso.**

Writers describe this "gastric vertigo" as distinct from other varieties of giddiness. It may be that the stomach is not so often concerned in the production of vertigo as the so-called bilious condition which Dr Murchison identified with lithæmia. But without deciding this point the question is whether the giddiness due to disorders of digestion is different in kind from that which depends upon deafness. Dr Wilks has remarked that the vertigo caused by derangement of the liver occurs chiefly when the patient stoops or lays his head upon the pillow, and ceases when he stands upright. But this distinction is not constant; and in many cases there is nothing in the nervous symptoms themselves to show that they depend upon one rather than another of the various causes to which they may be due.

In some cases the ingestion of food which disagrees with the patient leads so quickly to swimming in the head that the connection cannot be overlooked. Dr Murchison speaks of a medical friend of his, who has long suffered from gout, and who, whenever he drinks a cup of tea or a glass of champagne, is seized with sudden giddiness; his head feels empty, and neighbouring objects seem to whirl about him; he would fall did he not lay hold of something to support him; after a few seconds or minutes the attack passes off. In other patients the vertigo lasts longer. Dr Ramskill relates the case of a merchant who was one day quietly walking in the City from one office to another, when he was seized with giddiness, so that he reeled, and had to lay hold of a post which was near at hand. In a few hours, after a free evacuation of the bowels, he became better, but he felt weak and shaken, and complained of a heavy diffused headache. About three hours before the attack he had eaten hastily, and with imperfect mastication, a breakfast of which sausages and Devonshire cream formed a part; and to this the vertigo was ascribed, no doubt with justice. Yet, during the following month, the same patient had five similar attacks, not one of which could be traced to any such cause, he having in the meantime become very particular as to his diet. Dr Ramskill goes so far as to say that in "stomach vertigo" it is the exception if one is able to trace any positive signs of gastric disorder: the proof is that the complaint is cured by treatment directed to the regulation of the digestive organs. Thus, a second medical friend of Dr Murchison's, who had never had gout, and in whose case the only recorded indication of lithæmia was that his urine was often loaded with lithates, was seized with dimness of sight every night while writing. He took iron and quinine and other tonics, but without any benefit. He was advised to give up practice for a time, and try the effect of a change of air; but while he was making up his mind to so serious a step, he took a few

* "I was seized with so cruel a fit of that giddiness" ("and weakness and sickness in my stomach") "which at times hath pursued me from my youth that I was forced to lie down on a bed for two hours" (Dec. 17, 1734).

grains of blue pill, whereupon his symptoms at once disappeared. So, again, Trousseau quotes from Boerhaave the case of a man who, during two years, was seized with symptoms of vertigo whenever he attempted to stand up. In vain had the ablest practitioners attempted to cure him. He had a first attack of gout, and from that time the giddiness ceased.

To complete the chain of evidence which proves that vertigo is one of the paroxysmal neuroses, there remains the fact that it may replace other members of this group. Giddiness is occasionally present during the paroxysms of migraine; and Dr Liveing refers to two cases, in each of which an attack of intense vertigo, of short duration, appeared several times to replace the ordinary sick headache. The connection of vertigo with epilepsy is, perhaps, closer still; for giddiness is one of the symptoms of the *petit mal*.

There are, however, cases in which this neurosis is idiopathic and remains unchanged in type for many years. Dr Ramskill states that he has met with two instances of this "essential" vertigo in which the complaint appeared to be transmitted by inheritance. One of his patients suffering from vertigo had a father living, and then aged seventy-one, who had himself been subject to it for thirty-five years; he also had asthma. Another patient complained for three years of giddiness for which no cause could be discovered, and which resisted all kinds of treatment. It is true that in that case the giddiness after a time became almost continuous; and *persistent* vertigo is probably more often due to anæmia from disease of the arteries of the brain than to any other cause. But it seems probable that in exceptional cases any of the paroxysmal neuroses may at last cease to be interrupted by intervals. For example, a case is recorded by Charcot ('Progrès Méd.,' ii) of a woman, aged fifty-one, who had for six years suffered from continuous vertigo, which did not intermit even at night, and was so severe that she could not walk, nor even stand, for the slightest movement of her head made her clutch at surrounding objects for support. The complaint had lasted twenty-six years; but for a long time it was purely paroxysmal. She had disease of the tympanum on each side.

In the *treatment* of vertigo bromide of potassium is of more service than any other medicine, and its value is sometimes more striking than even in epilepsy itself.

The aural surgeons use chloride of ammonium for those cases which are associated with deafness. We have lately (April, 1890) had a marked case of paroxysmal vertigo, with severe headache, tinnitus, and temporary deafness with vomiting, but with no evidence of organic disease of the brain or the ear, in Philip Ward. The patient, a man of about fifty, had been subject to the attacks for several months, and recovered rapidly under moderate doses of bromide.

A careful inquiry must be made for symptoms of dyspepsia or of lithæmia, and Dr Ramskill recommends that alkalies and vegetable bitters should be used in all cases on the chance of their being of service. It is a good plan to give the bromide with a few grains of carbonate of soda, and with equal parts of the infusions of rhubarb and calumba. Wine is valuable in senile vertigo. Charcot's patient was cured in from two to three months by fifteen grains of quinine daily; but in a very characteristic case of auditory vertigo lately under the writer's care the patient had, by Professor Charcot's advice, taken quinine in full and repeated doses without the least benefit.

PAROXYSMAL MANIA.*—There is a paroxysmal neurosis in which the attacks take the form of transitory mania.

A striking instance is recorded by Dr Maclaren in the 'Medical Times and Gazette' for 1876. The patient was a slight, gentle-looking lady, aged forty-three, with winning manners and a soft quiet voice. She was characterised by exalted religious feelings and morbid sensitiveness. She would be reading her Bible and talking gently to her attendant, when suddenly, without a moment's warning, she would throw the book out of the window, and make a rush to run her head into the fire; or she would, perhaps, turn on the attendant and try to strangle her. She would then struggle on, keeping all the time perfectly silent, or uttering only an occasional word of Scripture, until she was exhausted, or until by a kind of awakening she became restored to her former condition. Sometimes in the attacks she would expose her person. During the intervals she had no recollection whatever of what she had done; at the most she could slightly recall the impulse which led her to attempt some act of violence.

One peculiarity of the paroxysms in this case was that in each of them the patient made efforts to get at one particular picture, which at other times excited no emotion whatever. Thus it seemed that she followed out in successive attacks trains of thought of which she had no knowledge during the intervals; and her condition might so far be termed one of "dual consciousness."

Although Falret described this disorder as *furor epilepticus*, it would appear that a liability to epilepsy is not always present. Dr Maclaren's patient had never had epilepsy, although she was a member of a family in which neurotic affections prevailed; but there is no question that the affection is one which bears a very close relation to epilepsy. As a rule, patients who have seizures of this kind have before suffered from attacks of the *petit mal*, if not of the *haut mal*. Dr Hughlings Jackson, indeed, has expressed the opinion that a transitory epileptic paroxysm really occurs each time before the mental symptoms develop themselves. In other words, he thinks that the affection is identical with that form of mania which sometimes follows an epileptic fit (p. 754). This view rests upon a theoretical basis. He supposes that a necessary condition for the occurrence of the mental disorder is the removal of the control of the highest centres, which are exhausted by having discharged themselves during the fit.

Even when paroxysmal insanity occurs in those who are really subject to frequent epileptic fits, one may be unable to ascertain the fact at the time. It often happens that a patient in this condition is brought to a public hospital by the police, and, as Dr Jackson remarks, it may be impossible for one to say whether he is an epileptic, or drunk, or suffering from meningeal hæmorrhage. He records an interesting case of a woman who was brought to the London Hospital in a maniacal state, with a deep gash in the left arm, by which the elbow-joint was opened, and all the soft parts in front of it were cut through. She accused different people of having inflicted this wound upon her, but it was ascertained beyond doubt that she had done it herself. She had been cutting bread for her children's tea when she suddenly sent them all out of the room. A short time afterwards she was found lying in a pool of blood on the floor. On the following day she was rational, but furious mania returned several times during the next week.

* *Synonyms.*—Epileptiform mania — Paroxysmal insanity — Furor epilepticus.—*Fr.* Folie circulaire.

On inquiry it was ascertained that she had been subject to epilepsy, in both the minor and the graver form. The patient doubtless received the suggestion which led to the infliction of the wound from the circumstance that she had a knife in her hand at the time.

The sufferer from this form of insanity is particularly liable to find himself in the hands of the police for some offence committed during the paroxysm; and although to a skilled medical observer it may be perfectly evident that he is irresponsible, there may be much difficulty in making this clear to others. Dr Jackson has done much towards the elucidation of such cases by studying other instances in which the acts performed are not criminal but absurd; they may be characterised by precisely the same degree of adaptation of means to ends, and yet they leave no trace on the memory. Thus one of his patients had been talking about supper, and it had been agreed that he and his wife should have some cold fowl, and her sister some cocoa. Soon afterwards he felt the symptoms of an attack and sat down on a chair against the wall of the kitchen, where he happened to be. He remembered nothing further, but his sister-in-law came in and found him standing by the table mixing cocoa in a dirty gallipot, which was half filled with bread and milk for the cat, and stirring the mixture with a mustard-spoon, which he could not have obtained except by going to the cupboard for the purpose. If the object fetched had been a knife, and if he had inflicted some injury with it, this purposive action would have seemed a strong point against him.

Dr Jackson, however, himself admits that the form taken by a man's mental automatism during the paroxysm depends very much on his natural disposition. A savage and suspicious man would, when his highest faculties were temporarily in abeyance, be more likely to kill some one than to mix cocoa for his sister-in-law. Indeed, the actions performed during a state of unconsciousness are sometimes exactly those which would have been performed if the individual had been in full possession of his faculties. The patient last referred to had on another occasion ordered dinner at an eating-house, when his mental condition underwent a change, and he remembered nothing more until he found himself at his desk in the office, feeling rather confused. He had to go to the place and ask whether he had had his dinner, and he then found that he had eaten it and paid for it, and that neither landlady nor waiter had noticed any peculiarity about him.

In other cases the patient goes through ordinary actions in an absurd way. Thus another of Dr Jackson's patients, while in an omnibus, was one day observed to blow his nose upon a piece of paper, and when he got out he gave the conductor £2 10*s.* instead of the usual coppers. The same physician had a patient, who one day found the extinguisher of a candle in his waistcoat pocket. For some years he invariably looked at his watch after each fit, and the supposition is that he must, in an attack, have mistaken the extinguisher for his watch.

Falret long ago remarked that an impulsive tendency to wander about is characteristic of this form of insanity. Hence the name used by some French writers of *Folie circulaire*. Trousseau gives some instances. A gentleman was attending a literary meeting at the Hôtel de Ville, when he ran out and walked for some minutes on the quays, avoiding with success both the carriages and the passers by. When he recovered he found that he had neither great-coat nor hat; he returned to the room and resumed, with a perfectly lucid mind, the historical discussion in which he had before

taken an active part. The same gentleman, being a magistrate, was presiding at a provincial tribunal, when he suddenly got up, muttered a few unintelligible words, and went into another room. He was followed by the usher, who saw him make water in one corner, after which he returned to his seat. Another patient of Trousseau's, an architect, used often to have an attack while walking across a narrow plank at a height from the ground. He never met with any accident, although he would run rapidly over the scaffolding, shrieking out his own name in a loud abrupt voice. A moment afterwards he would resume his occupation and give orders to his workmen, without any recollection of what had occurred to him.

In attacks of this kind the state of the patient is often said to be that of a man walking in his sleep. True somnambulism (when it is not a manifestation of hysteria) has every claim to be regarded as a member of the group of paroxysmal neuroses (cf. *infra*, p. 819).

The same is the case, too, with the "night terrors" to which some children are liable, who start up an hour or two after going to sleep, screaming with fright, and unable for some minutes to recognise the parents or nurse. That these various attacks should occur only at night is nothing more than occurs in many cases of epilepsy itself.

MEGRIM.*—*Definition and nomenclature.*—An attack of this disease in its most typical form begins with a peculiar dimness of sight; after a while the fingers of one hand become numb and tingle, or the patient feels some difficulty of speech; presently the power of vision is restored, but pain in the head comes on, which may last for some hours, and, before it ceases, vomiting often takes place. The same succession of symptoms recurs again and again at more or less regular intervals.

Great confusion prevails with regard to the nomenclature of this complaint. Many names for it are in use, but each of them is properly applicable to only one of the various forms it may assume, and several of them would naturally be taken to include other and distinct affections.

The pain is often limited to one side of the head. To such cases the name "hemicrania" has been applied since the days of the old Greek writers; and that word has undergone corruption into the French *migraine* and the English *megrim*. In strictness, therefore, these terms are inapplicable to a case in which both temples ache at the same time; but such cases constitute the majority, and cannot be separated from the others. Still less can those be isolated in which the pain is intense and limited to a single point, as if a nail were driven into the skull—*clavus hystericus*.

Lastly, we have the English terms *bilious headache*, *sick headache*, and *sick giddiness*. But many cases present no indication of gastric or hepatic disorder; and there is a different form of headache far more closely related to dyspepsia and constipation. If we can forget its etymology, the word megrim or migraine is the most suitable general term, and Dr Liveing thus adopted it.

Symptoms.—There is one symptom of megrim which invariably precedes all the others if it occurs at all; this is the *affection of sight*. The patient first notices that he cannot see distinctly some part of what he is looking

* *Synonyms.*—Hemicrania (*ἡμικρανία*), whence *Fr.* Migraine, and our vernacular term, "the Megrims."—*Germ.* Hemicranie.—Paroxysmal sick headache—Bilious headache (in part)—Clavus hystericus—Hemicrania periodica and Hysteria cephalica refer rather to supra-orbital neuralgia than to Megrim.

at. The portion of the visual field which is thus blotted out is at first very small. It may be at the exact centre of the field, but more generally it is a little to one side of it, so that in reading from a printed page he has to glance slightly away from the word he wishes to see. The dim spot is not black, but seems like a faint cloud, of the same colour as the rest of the surface upon which the eyes are directed. It quickly begins to enlarge, and gradually overspreads more or less of one lateral half of the field. This symptom is known as Hemiopsia (cf. *supra*, pp. 573, 618, 682). Dr Hubert Airy has proposed to call it *teichopsia* (τεῖχος, a city wall; ὄψις, vision), from the peculiar zigzagged outline, with angles like those of a fortification, which often marks the edge of the blind half of the field. The surface within seems to have an undulatory motion which has been compared to that of a boiling liquid; and the angles appear to flicker or to revolve. The form of the cloud is originally oval, but as it grows bigger a gap forms in the side towards the centre of the field, so that it becomes horseshoe-shaped. One part of the curve then seems to touch the point of exact vision; and in this the angles are much smaller and closer together than in the other part, which spreads away into the outer region of the field. Sometimes the cloud is uncoloured; sometimes it presents brilliant gleams of red, blue, and other colours. If the eyes be closed, or if the person should go into a dark room with his eyes open, the whole figure appears to be faintly luminous. As it increases in size, the central part gradually clears up and accurate vision is regained. On a printed page, for instance, a few letters can now be plainly recognised in the midst of the glimmering horseshoe-like curve. Before long the latter likewise disappears, and the patient can see as well as ever. The whole process occupies from ten to twenty minutes, or at most half an hour.

While the oval cloudy patch and its zigzagged border are visible, they are seen in their minutest details by both eyes alike. To this rule a single exception has been recorded by Sir John Herschel, who once satisfied himself that his left eye was alone affected. But, as Dr Airy remarks, everyone is at first inclined to suppose that one eye only is concerned, namely, that of the side on which part of the visual field is blotted out. This fact, that the impairment of vision is referred to both retinæ, proves that the seat of the affection is above the optic chiasma. The limitation to one half of the field is just what we should expect from our knowledge of the anatomy of the nervous centres, the halves of which are in great measure isolated from one another, each communicating with corresponding halves of the two eyes. Sir John Herschel, indeed, has stated that in his own person he once observed "the shadowy pattern of a fortification which passed completely across the field of vision from left to right." If this was so, we must suppose that on that occasion the disturbance which is the cause of the affection extended over to the opposite side of the brain at an early period of the attack. We shall see that at a later stage this is not unusual.

In a few cases, as soon as natural vision is restored, the attack is at an end. But in the great majority a more or less severe headache comes on at this period. It is said that a precisely similar headache may also arise without having been preceded by any disturbance of sight.

A curious circumstance in regard to the visual affection is that some of the best and most careful descriptions of it have been written, not by physicians, but by astronomers and natural philosophers. Wollaston, Arago, Sir David Brewster, Sir John Herschel, Sir Charles Wheatstone, Du Bois

Reymond, Sir George Airy, and Professor Dufour, of Lausanne, were all liable to this paroxysmal defect of sight, and all carefully noted its phenomena; no similar malady has, within the present century, been the subject of two papers admitted into the 'Philosophical Transactions,' as well as of communications to the 'Philosophical Magazine' and other scientific journals at home and abroad. It may be a question whether persons who are not accustomed to employ the eyes for minute observation would notice the dimness of sight, or mention it to their physician. Indeed, when it begins at some distance from the centre of vision it is sure to be overlooked, unless the patient's attention is specially directed to it. This may, perhaps, be the reason why Professor Du Bois Reymond does not mention it in describing megrim from his own experience.

The *pain* of sick headache varies greatly in severity, both in different cases, and in the same case at different times. It commonly begins at some one spot in the brow or temple and gradually spreads over these regions. Sometimes it remains confined to a single point, which is generally over the frontal or parietal bone on one side. It was to these cases that the special name of *clavus* was formerly applied. A strict limitation, however, is very exceptional. According to Dr Liveing, it is not even the rule that the headache should keep to one half of the head. He finds that in the majority of cases it affects the whole forehead and both temples, although with more severity on one side than on the other. It often extends to the orbit, and is referred with special intensity to the back of the eye. More rarely it passes behind the ear to the occipital region. Some writers describe it as of a stabbing, cutting, or boring character; others as throbbing, and increasing with each beat of the heart. It is augmented by every bodily movement that the patient makes, by exposure of his eyes to light, and by every noise that he hears. He therefore lies down, and keeps the room as dark and quiet as possible. But Dr Wilks knows of one patient in whom the recumbent posture aggravates the pain, and who will sit up all night rather than lie down until the attack has passed off; and Dr Liveing speaks of cases in which the pain is so intolerable that the sufferer cannot lie still, but is obliged to get up and move about. It has been said that the patient can sometimes make the visual affection more marked, if not increase the headache, by lying on the side opposite to that on which the dimness of sight is observed; but this seems to be seldom the case.

The headache scarcely ever remains long at the same pitch of intensity. Generally it goes on gradually augmenting in severity until it reaches a culminating point, after which it begins to decline. Its increase is usually steady, but sometimes this takes place by fits and starts.

When the pain becomes intense the patient begins to feel *nausea;* and presently he retches and vomits. Anything that the stomach contains is rejected, including sometimes a considerable quantity of undigested food. If it is empty, the retching is ineffectual, or some mucus at first is brought up, and afterwards a bilious fluid. After the occurrence of free vomiting the pain often quickly passes off, and thus many patients regard it as curative, saying that they get well as soon as they are sick.

In some cases, however severe the headache may be, sickness seldom or never occurs. The pain gradually passes off of its own accord; but often it lasts for the rest of the day; the patient at length becomes worn out and drops off to sleep; and when he wakes on the following morning he finds only a slight soreness of the forehead or temple left. Some persons

lose the pain if they can sleep for a short time, even during the early part of an attack. Dr Liveing mentions a gardener who, if he could at the onset of an attack leave his work and lie down under the shade of a tree, would wake at the end of half an hour as well as ever. Lastly, in some rare cases the complaint terminates by epistaxis, by a copious secretion of tears, by profuse perspiration, or by an abundant flow of pale urine.

Less common symptoms.—An attack of megrim may be attended with exceptional symptoms. In certain cases, which are generally of considerable severity, common *sensation* is impaired in one hand, especially towards the ends of the fingers; and a feeling of tingling, thrilling, or formication may also be experienced. Sometimes the surface of all one arm and of the corresponding leg seems to have gone to sleep, or numbness may extend to the mouth, the lips, tongue, or throat. Dr Liveing says that all these parts are affected bilaterally. Dr Anstie noticed in his own person that, even in the intervals between the attacks of pain, the power of distinguishing impressions was permanently less in the skin round the inner angle of the right eye than on the opposite side; during and soon after the paroxysms the impairment of sensation was greater, and affected a larger area.

Occasionally *muscular power* seems to be more or less distinctly impaired. Ptosis and strabismus from paralysis of one of the recti muscles have each been present in cases which have been regarded by good observers as megrim. Some patients have been known to drop what they were carrying in the hand; but, as Dr Liveing suggests, this may be due to a loss of the sensations which should guide the muscles.

Another symptom which is occasionally present is *giddiness* or vertigo.

Again, in some cases the faculty of *speech* is disordered. The patient has difficulty in finding the expression which he wishes to use, or in constructing a coherent sentence. He may substitute one name for another; and an instance is recorded by Dr Liveing in which not a single word could be uttered. This may occur without any confusion of thought, or the patient may be painfully conscious that his memory is failing him, and that his intellect is embarrassed. Hallucinations are very rare; but there is often much mental depression, with a vague sense of anxiety and dread.

Such serious symptoms are uncommon, and generally commence before the headache, and after the affection of sight has continued for some time.

An oppressive *drowsiness* is sometimes noticed, so that the patient lies half unconscious, not heeding when he is spoken to; but this symptom rather accompanies than precedes the pain in the head.

In some instances there are indications that the vaso-motor nerves are implicated. The temporal artery becomes enlarged, and its tortuosities are much more plainly visible on the affected side of the head; it feels hard and like a cord to the touch. The conjunctivæ may be much reddened. The *pupil* is sometimes altered in size, but observers are not agreed as to the character of the change. Du Bois Reymond says that in himself it is always dilated; Piorry and Latham describe it as being contracted. The eyeball is said to appear retracted in some cases. In one instance Möllendorff found with the ophthalmoscope that the background of the affected eye was of a bright scarlet colour, the optic papilla red and œdematous, the central artery and the veins enlarged and tortuous. These facts seem to indicate that vaso-motor disturbance is concerned in the production of migraine.

After the subsidence of the paroxysms, certain very curious *trophic*

changes are sometimes observed, which can only be ascribed to an interference with their nutrition consequent on the nervous disturbance. One such change is a localised *greyness of the hair*. Anstie relates that when he himself had a severe attack of megrim the eyebrow would show a distinct patch of grey opposite the supra-orbital notch, but that subsequently the individual hairs regained their natural colour. He found that as many as eleven out of twenty-seven patients showed more or less greyness of the hair of the forehead and temple on the side on which they suffered most pain. In other cases the hairs become brittle or fall out. Some years ago the author was asked by a student to examine the hairs from his eyebrows with a microscope, to see if any fungus was present. More than half of each eyebrow, at its outer part, had become denuded of hair; and this condition was more marked on one side than on the opposite. On inquiry he was found to be liable to migraine, and it was more severe on the side on which the eyebrow was more deficient. In a few weeks, under treatment for the neurosis, the hair began to grow again.

According to Anstie, more or less thickening of the tissues occurs in many cases as the result of repeated attacks of migraine. He also speaks of iritis, glaucoma, opacity and ulceration of cornea, as resulting from neuralgia of the fifth nerve; but it is not certain whether such effects occur in cases of true recurrent migraine. An eruption like erysipelas ought, however, to be mentioned; for Anstie relates more than one instance in which a patient suffered from two or three successive attacks of this kind along with neuralgic pain. The upper eyelid is sometimes much swollen.

Another affection which is frequently consecutive to megrim is *xanthelasma* of the eyelids. It always begins near the internal canthus, generally in the upper lid; and (according to Mr Hutchinson) it constantly appears on the left side earlier than on the right. This observer found that most of the patients in whom he noticed xanthelasma of the eyelids had suffered from frequent sick headaches, some of them severely. This cutaneous affection seldom appears before the age of thirty-five or forty years.

The general *circulation* is interfered with in severe attacks of migraine. Möllendorff has found the beats of the heart reduced to fifty-two or even forty-eight per minute. The pulse at the wrist becomes small and contracted. The hands and feet are cold. The face is pale and haggard, and dark borders appear round the margins of the orbits.

The side affected.—It seldom if ever happens that megrim, in all its attacks in the same patient, attacks the same side of the head. As a rule, there is one side rather than the other which is more apt to be affected; but Tissot mentions the case of a lady who had it alternately on each side with great regularity. Wollaston and Sir George Airy may also be mentioned as having been equally liable to the affection on either the right or the left side. Dr Latham describes the headache as beginning, and as more intense, on the side *opposite* to that on which the dimness of sight is noticed, but Dr Liveing deduces from the observations which he has collected that they often both occur on the same side. Both authors say that when the affection of sight and the numbness in the fingers are present together, it is on the same side of the body. Lastly, Dr Liveing has pointed out the fact —interesting in connection with what has been said as regards aphasia from organic lesions—that when the speech is interfered with in migraine there is very generally numbness in the fingers, and that this always affects the right hand, either alone or in association with the left. He has not met

with a single instance in which sensation was impaired in the *left* hand only, together with any affection of the speech.

Pathology.—Megrim is undoubtedly one of the paroxysmal neuroses. As regards its anatomical seat, the disturbance which causes the affection of sight must occur somewhere above the optic chiasma. Indeed, this was long ago pointed out by Wollaston, who thought that the hemiopia which he described would probably be found to arise in the thalamus of one side. As Dr Liveing remarks, the only correction that this statement seems to require at the present time is to add the corpora quadrigemina, and to include within the area of disturbance in a fit of megrim the ganglia of the sensory nerves, down to the nucleus of the vagus. The order in which the symptoms follow one another in the several attacks renders it likely that the affection generally starts in the corpora quadrigemina or geniculata, and passes downwards and backwards along the sensory tract. The numbness and tingling may possibly be due to disturbance in the thalamus, and disorder of speech and impairment of memory seem to show that the "storm" has spread upwards to the convolutions. That it may also extend to the opposite side of the brain appears to follow from the facts that the numbness in the tongue and throat is sometimes bilateral, and the headache frequently so.

As to the exact nature of the change in the sensory tract which gives rise to migraine, nothing definite can at present be stated. The most recent hypotheses refer it to vaso-motor disturbance. Thus the theory of Dr Latham (1872) is that in the early stage the affected side of the brain is anæmic; that the contraction of the blood-vessels of this hemisphere is itself due to a morbid activity of the sympathetic nerve; and that this in its turn results from a defective control or inhibition on the part of the cerebro-spinal system, which he supposes to be enfeebled. In the stage of headache he supposes that there is a secondary hyperæmia, consequent upon exhaustion of the vaso-motor apparatus. Du Bois Reymond had previously (1860) maintained that, at least in his own case, migraine was due to tetanus of the muscular coats of the vessels of the affected side, in the territory of the cervical portion of the sympathetic. On the other hand, Möllendorff (1867) and Wilks (1869) believe that the complaint is caused by paralysis of the very same nerves, with dilatation of the vessels and consequent hyperæmia.* The former writer lays great stress on the fact (which had been pointed out nearly a century ago by Dr Parry, of Bath) that compression of the carotid on the affected side of the head often removes headache as if by magic, though only for a time. But diminishing the blood supply to one side of the brain may very well suspend for a time the disturbance which is felt as pain, and yet that disturbance may not have been caused by an overflow of blood. Moreover, as Dr Liveing points out, the statements of different observers with regard to the condition of the pupil are so diametrically opposed that no other inference seems possible but that it must really differ in different cases; while as for the dilatation of the temporal artery, the flushing of the face, the redness of the conjunctiva, the injection of the fundus of the eye, none of them is constantly present; so that the only possible conclusion seems to be that all these vaso-motor phenomena are only accidental, not essential characters. As Dr Liveing remarks, there is a clear analogy between the paroxysmal neuroses, and certain minor consensual and automatic movements, such as sneezing,

* Dr Eulenburg thinks that both theories are right, and that certain cases are due to spasm, others to paresis of the vaso-motor nerves.

coughing, and gaping, to which may be added ejaculatio seminis—a short convulsion, as it has been termed, and in certain cases accompanied by a true epileptic attack; yet no physiologist thinks of referring any of these to vaso-motor disorder.

Thus it would seem that at present we can form no clearer conception of an attack of migraine than that it is a "nerve-storm," or an "explosive discharge" of nervous irritability.

Ætiology.—The *hereditary* character of megrim is well marked. Dr Liveing found that in twenty-six cases out of fifty-three it was said to be a "family complaint;" and the twenty-six patients in question had among them forty near relations who were liable to it. In many cases it is transmitted without the slightest change of type, and sometimes it passes from a parent to those children only who in other respects resemble him. Sometimes, however, a daughter inherits megrim from an epileptic mother.

As to the relative liability of the sexes, women appear to be more prone to this complaint than men. Eulenburg believes that five women have hemicrania to one man.

The *age* at which it commences is generally about the seventh or eighth year, at the beginning of the second dentition, but sometimes it is the period of puberty, and sometimes that of early adult life. It rarely occurs for the first time in a person over twenty-five or thirty. The more marked the hereditary tendency the greater the probability of its beginning in childhood. At about the age of thirty, persons often suffer from it much more severely than before; and, as Anstie remarks, at this period the attacks cease in many instances to be accompanied by vomiting, so that the complaint is no longer regarded as mere "sick headache," and the patient consequently seeks medical advice, perhaps for the first time. When fifty years of age are reached, or somewhat earlier, the liability to migraine commonly ceases, and old people seldom suffer from it.

In some persons the attacks of migraine recur with regular periodicity. The period is sometimes a fortnight, sometimes a month, sometimes longer still. There are, however, cases in which it is much shorter.

The immediate exciting cause of the paroxysm is often excessive fatigue. Thus, a bank clerk had an attack regularly every week-day, but was free on Sundays; and a governess, under the author's care, had a headache every night. In cases of this kind some of the more characteristic features of the complaint are apt to be missing; but their relation to true migraine can often be established by the account which the patient gives of his previous state of health. Further observation may perhaps show that a headache which is persistent may grow out of the paroxysmal affection. If so, such a case would be strictly parallel to one of epilepsy, followed by the status epilepticus.

In the cases just referred to the complaint may return every day, or every other day, as regularly as the paroxysms of an intermittent fever; and this fact, together with the striking therapeutical influence of quinine, often makes it difficult to exclude the possibility of miasmatic poisoning. But these circumstances, taken by themselves, are far from justifying the conclusion that a case of migraine really deserves the name of "brow ague." It is probable that even in districts where malaria prevails, migraine and other forms of neuralgia are often wrongly ascribed to that cause. But it appears to be certain that it is sometimes really the cause; and in some parts of Spain a miasmatic migraine is said to be endemic. Dr Macculloch has stated that

this kind of headache may occur as a substitute for ague during the whole of one relapse of the disease, and that he has seen a "double tertian" ague, in which the headache and the ague fit occurred regularly on alternate days.

In England, it is universally believed that migraine, instead of being essentially a nervous malady, is the result of "*bilious*" disorder; and when the attack is accompanied by vomiting, this is supposed to expel a "*materies morbi*," in the shape of vitiated bile. Until one has happened to discuss the matter with some patient of intelligence, one can hardly conceive how firmly fixed is the belief in question. The truth is that it is a relic of one of the most ancient doctrines in the history of medicine, that of the four Cardinal Humours, one of which was "yellow," and another "black" bile.

Although it is certain that migraine is never solely due to disorder of the chylopoietic viscera, there is no question that some error of diet is often the direct exciting cause of an attack in a person who is liable to it. No doubt the diffused headache and giddiness which are apt to be more or less present in persons who suffer from dyspepsia or from the so-called congestion of the liver have been often confounded with true migraine. But what is conclusive as to the reality of the influence of improper food is the fact that some persons at least can always bring on an attack of the latter disorder by eating particular articles of diet towards the end of the interval between one paroxysm and another; whereas, for a few days after they might partake freely of the very same things without suffering in any way. Dr Fothergill nearly a century ago stated that he had found nothing more apt to cause "sick headache" than "melted butter, fat meats, spices, meat pies, hot buttered toast, and malt liquors when strong and hoppy." A medical man who had suffered all his life from the complaint told Dr Liveing that he could never take the smallest quantity of wine nor eat the smallest fragment of pastry without bringing on a headache. Many persons speak of butter and pork as particularly frequent exciting causes of migraine; and, making every allowance for the influence of preconceived opinions, it seems likely that such statements are not entirely imaginary.

In women, again, the recurrence of the *catamenia* is often an exciting cause of attacks of migraine, which, perhaps, generally precede the flux, but sometimes accompany or even follow it. Not infrequently each monthly period brings with it a series of more or less distinct paroxysms. Dr Liveing relates the case of a woman who was very liable to the complaint when menstruating, but who throughout repeated pregnancies was always entirely free from it. This writer also mentions an instance in which the headache and the catamenial discharge recurred simultaneously at fortnightly intervals.

But *fatigue* is a far more important exciting cause of migraine. In some persons a straining effort, such as lifting a heavy weight, will bring it on, and in others the exertion of running is apt to have the same effect. Many women are exceedingly liable to be attacked after a hard day's washing, or after a long walk. Another frequent cause is severe mental work; but, above all, anxiety and emotional disturbance. A long railway journey is apt to be followed by a paroxysm in some ladies, and in others merely driving in the streets of London has the same effect. Many persons always have a sick headache after a day's sight-seeing, or after passing an evening in a crowded concert-room or ball-room; and in some susceptible patients an attack may be brought on by glaring lights, loud noises, or strong odours. Dr Airy mentions the case of a person in whom the peculiar affection of sight was

occasionally caused by looking at a striped wall-paper or a striped dress; and Sir John Herschel found that he incurred it as the result of allowing his mind to dwell upon a description of its symptoms.

In several of the conditions already alluded to as exciting causes of migraine, one element is *visual exhaustion*; and this is true not only of over-study, but also of railway travelling and the like. Many years ago, Piorry propounded the theory that the complaint, or at least one variety of it, was the result of irritation of the optic nerves, from straining efforts to see very small objects, or from want of care in regulating the amount of light. This view is quite untenable if applied to all cases of sick headache. But it is perfectly true that when the eyes are structurally imperfect the forced effort to use them may be the immediate cause of attacks of migraine. The defects which lead to this result are chiefly those of the transparent or refracting media of the eyes; their direct effect is the production of spasm of the ciliary muscles, and with this is associated an irritation of nervous filaments, which may diffuse itself over a wide area within the distribution of the fifth nerve. Every practitioner now knows that hypermetropia is a frequent cause of attacks of dimness of sight, headache, and giddiness, which recur when the eyes are used for near work for any length of time, particularly under artificial light. A student suffering from similar symptoms discovered that they were the result of the employment of too powerful concave glasses, which he had chosen without proper advice, in order to correct a moderate degree of myopia, and which he wore even when reading or writing. In this connection, too, astigmatism must not be overlooked.

A less frequent cause of such symptoms is weakness of the internal recti muscles. The author once saw a bank clerk who had previously been compelled to give up work for a period of two or three months on account of cerebral symptoms. These had been thought very serious; but on examination by Mr Higgens it was discovered that the internal recti muscles failed to make the eyes converge properly upon near objects; and when suitable glasses were supplied he soon lost all his complaints. In practice, therefore, one should make it a rule never to prescribe for any kind of frontal headache without eliminating the possibility of its being caused by imperfection of the eyes.

Lastly, affections of the *teeth* must not be overlooked as causes of migraine, at least if clavus be included as a form of it (see p. 388). Mr Salter records the case of a young lady, who for eight years was subject to attacks of headache, confined to a space of about the size of a crown piece, rather to the left of the vertex. They sometimes recurred three or four times a week, beginning after breakfast and lasting all day; they were attended with great prostration. The affected spot became hot, and pressure with the hand gave relief. At length the patient fancied that the left upper canine tooth, which was known to be impacted in the palate, was in some way connected with her sufferings. It was removed, and she never afterwards was attacked by the headache.

Diagnosis.—In its typical form migraine presents little or no difficulty of diagnosis. In one or two cases syphilitic periostitis of the margin of the orbit has produced recurrent pains of somewhat similar character; but this could not escape the notice of any but a careless observer.

When the phenomena of the attacks are ill-developed, however, one may not find it easy to determine whether they belong to megrim, or to some other neurosis.

Several months before his death the late Dr J. J. Phillips had a

severe attack of headache, attended with marked aphasia. When he had recovered, the author one day happened to discuss with him the question whether it could have been of the nature of migraine; but his fatal attack of apoplexy, which doubtless was the result of embolism, began in precisely the same way, and with the same symptoms. It seems doubtful whether Dr Liveing is right in regarding as a mere paroxysmal neurosis a case in which attacks of loss of speech and right hemiplegia recurred, persisting for a week or more at a time.

Relation to other neuroses.—Migraine is so common a complaint that one can hardly attach much importance to the mere fact that some other neurosis occasionally develops itself in those who are subject to it, as indicating that there is any real relation between them. Dr Liveing, however, believes that a transformation sometimes occurs between megrim and epilepsy; and he relates cases in which persons who had suffered from the former afterwards became affected with the latter disease; but it is to be noted that some of them had relations who were epileptic. This writer also refers to an instance in which migraine became replaced after a certain period of asthma; and to another in which a constantly recurring gastralgia disappeared, and was followed by a typical migraine, while this in its turn was succeeded by a kind of spasmodic croup. He also relates a case in which attacks of sick headache were followed after a time by angina pectoris; and another in which insanity developed itself.

Probably no medical man can have suffered again and again from migraine without the thought being forced upon him that such attacks must indicate some serious defect of cerebral organisation; and Dr Liveing quotes Calmeil as having remarked that both the intellectual faculties and the moral disposition of the patient are sometimes impaired by the repeated occurrence of migraine. He also refers to the cases of Parry and Wollaston, both of whom, after having long been subject to this complaint, died of organic cerebral disease. But such results are extremely rare and probably accidental.

Treatment.—This includes: (1) the management of the patient during the intervals between the attacks, so as to prevent their occurrence or diminish their severity; and (2) the treatment of the paroxysm.

(1) Under the first head hygienic measures are of primary importance. One must insist upon the importance of daily exercise, short of fatigue, in the open air; one must prohibit an excess of mental work, and take care that the patient is as far as possible shielded from domestic anxiety. The state of the digestive organs must be carefully inquired into; and due weight must be allowed to any indications of dyspepsia or lithæmia, or to evidence that the attacks are brought on by errors of diet. But in many cases it is a mistake to restrict the patient too closely to what is termed plain food. Rather he should be advised to take a freer quantity of fat, in the form of butter or cream. Alcoholic beverages, however, should generally be avoided, or sparingly indulged in. In severe cases a change of climate is often advisable, and particularly a sea voyage.

One of the good results which may be anticipated from the discussions which have taken place as to the nature of migraine is that those who have the medical charge of young people will look out for the early manifestations of the complaint during childhood or puberty, and insist upon the avoidance of over-study and of undue excitement in those who seem likely to suffer from it. Until recently migraine was almost universally

looked upon as being at once incurable, and almost unworthy of notice on the part of a physician. But the truth is that if systematically taken in hand it is very amenable to treatment; and those who suffer from it know best how serious a matter it is to them, interrupting, as it frequently does, all the engagements, the pleasures, and the duties of life.

Among medicinal agents Dr Liveing says that he has sometimes found the regular administration of belladonna and hyoscyamus of great service. Cannabis indica also may frequently be prescribed with decided advantage; but bromide of potassium is perhaps still more generally useful.

In many cases the preparations of iron (especially the peroxide and the saccharated carbonate) are very serviceable, and this even though there may be no anæmia. Strychnia in small doses (one twentieth of a grain) is said to be another valuable remedy. The author has prescribed arsenic with marked success; it was long ago recommended by Dr Bright and Sir Thomas Watson. Quinine is said to be less serviceable than it is in many forms of neuralgia, except in cases of malarious origin.

There are other medicines of which the good effects are less readily intelligible. One such is iodide of potassium. Dr Todd is said to have found this more successful than anything else; and Dr Liveing mentions a case in which the attacks were so frequent and severe as to render the patient's life a burden to him, and in which five grains of the iodide three times a day set him almost free from them. In other cases chloride of ammonium seems to answer better than anything else. Valerian and valerianate of zinc are said by Dr Liveing to be sometimes of great value.

(2) The treatment of the paroxysms of migraine must necessarily depend on their severity; it is only in very violent attacks that the patient is likely to seek for medical advice. Of his own accord he will keep in a darkened room and maintain absolute quiet. If the feet be cold, they should be wrapped in blankets, and a hot bottle should be placed in contact with them; or they may be immersed in hot water to which some mustard has been added. Hydrate of chloral may then be administered in a dose of from twenty to thirty grains. Dr Anstie speaks of it as being of the greatest possible value in quickly bringing sleep to the patient, who when he wakes up may be free from pain. In some cases, and particularly when connected with neuralgia of dental origin, butyl-trichlor-aldehyde-hydrate ("croton-chloral") is still more decidedly efficacious. Bromide of potassium also is very useful; a scruple, or half a drachm, taken when the sight begins to be affected, sometimes cuts short the attack. At this period a cup of strong tea or coffee is in some persons capable of producing the same effect; even sipping hot water gives relief in some cases. Guarana—prepared in Brazil from *Paullinia sorbilis*—has been recommended by Dr Wilks: half a drachm of it may be taken, mixed with water; or about twenty or thirty minims of the liquid extract. Even this, however, is sometimes altogether useless. Dr Anstie mentions the extract of cannabis indica in a dose of a quarter to half a grain as being very serviceable in the migraine of the young; he says the dose should be repeated in two hours if sleep be not obtained. In some cases a full dose of brandy or a glass of sherry or champagne is very effectual; but there is always danger in allowing a patient to fly to such remedies for the purpose of allaying pain.

Antipyrin, in doses of from two or three to seven or ten grains, has lately been much used for sick headaches, and in some cases it is undoubtedly

efficacious. The patient should take it in hot brandy and water, and lie down for half an hour before taking a second or third dose.

Locally some measure of relief may be afforded by the pressure of a handkerchief tied tightly round the forehead.* Dr Liveing mentions a case in which plunging the head into cold water was often effectual. In some cases it has been found advantageous to apply to the seat of pain a little piece of cotton wool, on which a few drops of ether have been poured, and to cover it with a watch-glass; and bisulphide of carbon has been used in a similar manner. Some patients find great relief from rubbing a stick of menthol into the skin over the seat of pain. Trousseau speaks highly of the application of extract of belladonna to the painful temple; and Anstie says that a diluted ointment of veratria is often serviceable.

Another measure which appears sometimes to be highly successful is the application of the constant galvanic current. Anstie recommends that it should be passed from one mastoid process to the other. Only three or four cells should at first be employed, and never more than ten; it should be applied for but half a minute at a time, and repeated once or twice a day. Giddiness is very apt to be produced unless it be used with great caution.

* "When your head did but ache,
I knit my handkerchief about your brows."
King John.

NEUROSES OF THERMIC AND TOXIC ORIGIN

SUNSTROKE, AND THE EFFECTS OF DRINK AND OPIUM

"And when the child was grown, it fell on a day, that he went out to his father the reapers. And he said unto his father, 'My head, my head!' And he said to a lad 'Carry him to his mother.' And when he had taken him, and brought him to his mother he sat on her knees till noon, and then died."—2 *Kings*, iv.

"O that men should put an enemy into their mouths to steal away their brains!"
Othello.

"I paused seasonably: but with a difficulty that is past all description. Nothing short of mortal anguish in a physical sense, it seemed, to wean myself from opium; yet, on the other hand, death through overwhelming nervous terrors, death by brain fever, or by lunacy, seemed too certainly to besiege the alternative course."—DE QUINCEY.

HEAT-STROKE.—*Origin and pathology—Symptoms of the cardiac and cerebro-spinal forms—Prognosis—Sequelæ—Diagnosis—Treatment.*
ALCOHOLIC NEUROSES.—*Delirium tremens—its symptoms and course—prognosis and treatment—Chronic alcoholic poisoning—its symptoms and course—antecedents—diagnosis and treatment.*
NARCOTIC NEUROSES.—*Opium-eating—The morphia habit—Symptoms and results—Treatment—Neuroses due to other narcotic drugs.*

BEFORE concluding the long series of functional disorders of the nervous system, we must find room for two which are both acquired, and are both the direct result of external disturbing causes, namely, heat and alcoholic drinks. The ætiologically allied neuroses produced by metallic poisoning have already been noticed (pp. 519—523), but those which attend the abuse of opiates will be most conveniently discussed in the present chapter.

HEAT-STROKE.*—That exposure to intense heat is sometimes followed by alarming or fatal cerebral symptoms is now well known. The affection is not uncommon in the hotter parts of India, and it now and then occurs during the summer in England. It is also frequent during the hot season in New York and in Australia. The common term "Sunstroke" is inaccurate, for the direct rays of the sun are not required to produce it; it often comes on at night, when the temperature is very high, particularly when a number of persons are crowded together, as among soldiers in barracks, or sailors or emigrants on board ship. Sir Joseph Fayrer mentions it as occurring to the stokers in the engine-rooms of the Red Sea steamers. *Heat-stroke* is therefore a better name.

As might be expected, this disease often attacks several men simultaneously or in rapid succession. Dr Maclean speaks of having seen a great many soldiers of the 98th Regiment struck down, of whom about fifteen died on the spot, in taking possession of a steep hill in China in 1842. But the men who suffer from heat-stroke appear to be never more than a minority of those who are exposed at the same time to the sun's rays.

* *Synonyms.*—Solis ictus—Insolatio—Sunstroke—Heat-apoplexy.—*Fr.* Coup de soleil—La calenture (in part).—*Germ.* Hitzschlag, Sonnenstich.

This depends upon the fact that the disease is due to the failure of those natural processes which should enable the human body to resist the action of excessive heat. Dr Maclean remarks that the closely shaven heads of the Chinese bear the hottest sun without ill effects, although it is true that they generally use their fans to keep up a free current of air about their faces. Sportsmen in India expose themselves to very high temperatures with comparative impunity so long as they take care to wear light clothes, to protect the head and the spine, and to abstain from stimulants. Thus it is of the highest importance that soldiers and others who have to bear fatigue in hot climates should be suitably dressed, and should have no accoutrements which can interfere with the play of the lungs. More than one observer has noticed that large and fat men are especially apt to suffer from sunstroke, and that exhaustion from prolonged exertion is a predisposing cause. Other factors which are believed to be often concerned in its development in those who are not directly exposed to the sun are overcrowding and defective ventilation. It would seem to be more likely to occur when the air is loaded with moisture, since this must interfere with evaporation from the skin; but there was extreme dryness at the time of an outbreak which Surgeon-General Longmore saw at Barrackpore. Europeans are supposed to be more likely to suffer from the disease when they have been only a short time in India, but there is good evidence that natives are by no means free from it.

Symptoms.—The phenomena of heat-stroke vary in different cases.

(1) There is a "cardiac" form. In this death may be almost instantaneous by syncope, the man falling down suddenly insensible and making only a few hurried gasping respirations. Dr Morehead also describes milder cases, in which a sense of prostration and faintness is experienced, with vertigo, dimness of vision, dilated pupils, and drowsiness. The patient can be roused by speaking to him, pinching him, or sprinkling his face with cold water. There is constriction of the chest, with sighing respiration, a sense of weight or sinking at the epigastrium, nausea, and sometimes vomiting. The face and lips are pale. The skin is generally cold and clammy, with the exception of the head, which is somewhat hot. The pulse is feeble, and it is generally slow. Under judicious management such cases often recover; but sometimes the pulse sinks, the breathing becomes more sighing and irregular, and death occurs, being perhaps preceded by convulsions. "Cardiac" cases seem to be met with only among those who are attacked in consequence of direct exposure to the sun's rays. When recovery takes place, it is complete and leaves no sequelæ.

(2) There is a "cerebro-spinal" form, of which coma is the principal feature. This often comes on gradually. It may be preceded by nausea and loathing of food, giddiness, congestion of the eyes, extreme debility, and (as more than one observer has noticed) an unusual frequency of micturition. "I cannot hold my water" is said to have been in a large number of cases the first thing complained of. Dr Maclean speaks of the attack beginning with a wild shout of laughter, or with a delirious attempt to escape from an imaginary enemy; headache, he says, is seldom present. When heat-stroke occurs in a man sleeping in barracks, what draws the attention of his comrades to him is often his stertorous breathing. He is then found to be already insensible, with contracted pupils, deeply congested conjunctivæ, and a quick sharp pulse. As far back as 1860 Dr Morehead pointed out that the skin continued pungently hot to the close

of these cases, and even for some time after death. More recently, since the introduction of the thermometer into practice, it has been shown that the condition is really one of hyperpyrexia; and, in consequence, the name of "thermic fever" has been proposed for them. Three instances of this variety of the disease occurred in 1876 at Bristol, and were fully recorded in the 'Lancet' by Dr Shingleton Smith and Dr E. L. Fox. One of them was in a man, aged forty-five, who had been turning a winch on board a steamship, exposed to the full glare of the sun, from 8 a.m. The temperature in the shade was from 92·3° to 96°. At one o'clock he felt unwell, and began to talk incoherently and to throw his arms and legs about. He had been drinking water freely. He was admitted into the hospital half an hour later, and he was then comatose, with pin-point pupils; the temperature was 107°; the pulse 160, weak and intermitting; the breathing laboured; the face not flushed; the skin sweating. At twelve minutes past two the thermometer registered 109°. Under energetic treatment the temperature gradually fell to 100·4°; the pupils became normal and afterwards dilated; but the pulse failed more and more until it could not be counted, and at 7.40 he died. On the very same day, another man, aged thirty-five, was taken into the same hospital in a state of only partial consciousness, with general muscular tremor, soon followed by convulsions and opisthotonos. His temperature was then 110·2°; his pulse was too rapid and too feeble to be counted. He died twenty minutes later, the thermometer at that time registering 111°. Two days afterwards, a third case was admitted at 2.30 p.m. in the person of a man, aged fifty-five, who had been driving a hearse, when he fell backwards, and the reins dropped from his hands. He was comatose; there was tonic spasm of the muscles of the legs; the pupils were contracted, but sensible to light. The temperature at 2.40 was 106·4°; at 2.50 it was 107°. The pulse was 141; the breathing was stertorous and at the rate of 27 in the minute. Under treatment the temperature quickly fell; at 3.25 it was 102°, at 3.40 it was 100°. In this instauce recovery took place. These three cases appear to have presented all the chief symptoms of "thermic fever," as it is described by those who are familiar with sunstroke in India.

Dr Morehead speaks of a "mixed form" of heat-stroke, in which the symptoms are a variable combination of those of the other two forms.

Sir Joseph Fayrer distinguishes syncopal, asphyxial, and hyperpyrexial varieties of heat-stroke as observable in India.

It is well known that *sequelæ* of a very serious kind are not infrequent. Those mentioned by Dr Maclean are persisting headache, either fixed or shifting; a chorea-like affection of the muscles, generally those of the forearms and hands; epilepsy, particularly in those who have inherited a tendency to that disease, or have had fits in youth; and mental weakness.

Fatal event.—When heat-stroke ends in the patient's death, this generally occurs within nine hours, but sometimes not until towards the end of the second day. The average mortality of the disease is estimated at from 45 to 50 per cent. Fatal relapses, after recovery from incomplete coma, are not infrequent; cases which seem to be doing well require to be carefully watched with the thermometer until the skin becomes moist and cool.

Anatomy.—The usual *post-mortem* appearances are those of congestion of the viscera generally. The blood is said always to remain fluid. In twenty-five cases of death, out of forty-eight of heat-stroke, among the troops at Assouan in 1886, Surgeon Douglas Hunter remarked the following condi-

tions after death :—intense lividity of the surface and ecchymosis of the conjunctivæ ; venous engorgement ; muscles of dark colour : in only one case was meningitis observed. When meningitis is produced by the sun's heat (pp. 701–2) the cases seem as a rule to be distinguished by there being an interval between the time of exposure and the onset of symptoms.

In 1856 there was in Guy's Hospital a sailor who four years previously, when crossing the equator, had been attacked by sunstroke in company with another man who died. He himself came to in a few hours, but he could not speak for a month afterwards, and for a time he lost the use of his right arm and leg. From all these symptoms, however, he had perfectly recovered ; and he was now suffering from renal dropsy, which at length proved fatal. At the autopsy Dr Wilks found the arachnoid opaque and marked with white spots, the ependyma granular, and an excess of fluid in the brain. It is to be noted, however, that the vessels at the base were much diseased, so that the other morbid appearances may have been unconnected with heat-stroke.

Diagnosis.—Heat-stroke is no doubt easy to recognise in most cases ; but this often is because the patient is known to have been exposed to a high temperature, rather than because the symptoms are in themselves distinctive. Maclean places reliance on certain characters of the pulse and of the respiration, and on the state of the skin and of the pupils in apoplexy, as serving to exclude that disease from consideration. Probably there need be no doubt as to the real nature of those cases in which there is hyperpyrexia from the very commencement. But this is not always present ; and probably a person attacked on a hot day in India with cerebral hæmorrhage, or embolism, would be exceedingly likely to have his case set down as one of "sunstroke," even by good observers, especially if there were no paralysis.

Apart, however, from the classical coup de soleil or thermic fever of India and the tropics generally, there is a very much milder malady which is probably due to exposure to the sun, and is most often seen in children in England. A boy, after playing in the sun, will come in complaining of feeling sick and faint ; he may perhaps vomit, looks very pale, and has a bad headache. Cool drinks and rest in a dark room generally set him right in a few hours.

It often happens that patients tell one that their complaints all result from a "sunstroke" which they had in England during the previous summer ; but such statements must be received with caution.

Treatment.—The most important remedy is the bold and immediate employment of cold. Ice should be applied to the head ; a stream of iced water may be passed through coils of elastic or leaden tubing (as used by Leiter for the purpose) in contact with the back and the chest ; cold water must be poured over the head and neck and chest for a few minutes at a time. If the patient can swallow he should be allowed to drink freely. In the one successful case at Bristol (which, however, was less severe than the others) Dr Fox, besides applying cold, injected a grain of quinine under the skin in five different places ; and at the end of half an hour the patient took ten grains of quinine by the mouth. Indian practitioners are agreed that venesection is likely to be injurious rather than useful. Dr Hunter recommends a large enema and a dose of calomel.

When, however, the circulation fails, hot-water bottles must be applied instead of, or in succession to, the ice ; and brandy or liquor ammoniæ (♏viij to ʒiss of water) may then be injected subcutaneously. Dr Maclean

says that the application of a blister to the nape of the neck, or to the shaven head, may be of service. Artificial respiration should be resorted to in the asphyxial form of sunstroke. When convulsions set in, the inhalation of chloroform is recommended.

For *sequelæ* of heat-stroke, occurring in a person living in a hot country, removal to a temperate climate appears to be the best treatment. Dr Maclean states that at Netley there are always some cases of this kind, and that they are often very obstinate. He has seen long-continued counter-irritation to the nape of the neck, and a course of iodide of potassium relieve permanently some patients troubled with severe fixed pain in the head; but in other instances these measures have altogether failed. He gives a favourable prognosis for those who come home with epilepsy under such circumstances, as he has usually found the fits subside.

ALCOHOLIC NEUROSES.—Intemperance in drink may affect the nervous system in two ways—acutely as a form of delirium, and in a more insidious but scarcely less dangerous manner.

*Acute alcoholic poisoning.**—In many cases the nervous symptoms of alcoholism take an acute form, and one that may quickly endanger life. They then constitute a disease which has for many years been known under the name of "delirium tremens." The earliest account of it appears to have been published in 1813 by Dr Thomas Sutton, of Greenwich; and the first writer to describe its course, when not disturbed by the administration of medicine, was an American physician, Dr John Ware, of Boston, in 1831; his work, based on the observation of nearly a hundred cases, is perhaps superior to any that has since appeared.

Symptoms.—The patient has for two or three nights been more disturbed by unpleasant dreams than usual, and has by day become more restless and tremulous. At length he is altogether unable to sleep, but as he lies awake his dreams still haunt him. Next morning he may again be rational, but his mind almost always wanders occasionally. Towards evening the delirium returns, and the second night is worse than the first. During the second day there is again a slight amelioration as compared with the night, but the mental disorder is now fully established and persistent.

The delirium in this disease is in many respects peculiar. The patient is not fierce nor violent, nor, on the other hand, is he depressed in spirits and dull in manner. He is loquacious and restlessly anxious to follow his accustomed vocation, but he sets about his business in a blundering manner, and his mind quickly wanders away to something else. If spoken to, he is sufficiently intelligent to answer, and for a minute or two he may converse rationally, but before long he starts off on some fresh topic. His friends probably endeavour to keep him in bed, but he is always wanting to get up and dress himself. Yet, if firmly opposed, he forgets his intention, at least for the time. He commonly has hallucinations of vision. Very often he fancies that rats and mice, or snakes, or cockroaches, are running or crawling over his bed. Or he may address persons who are really absent, but whom he supposes to be in the room. He looks suspiciously behind the curtains or under his pillow, or stretches himself out of bed to see if some one is not concealed beneath it.

* *Synonyms.*—Delirium tremens—Delirium potatorum.—*Fr.* Intoxication alcoolique.—*Germ.* Säuferwahnsinn.

His hands are in constant motion. He picks at the bedclothes, or grasps at imaginary objects. If asked to put out his tongue, it is very tremulous, and is quickly withdrawn; it is commonly moist, and more or less thickly coated. The pulse is quick, soft, and feeble. The skin is moist and often in a state of profuse perspiration. There is an entire absence of appetite and even of desire for drink. As was pointed out by Dr Bence Jones, the amount of phosphates in the urine is very greatly diminished.

Event.—The duration of these symptoms is not absolutely constant, but it is far more regular than is generally supposed. The disease almost always goes on for two and a half days without showing any tendency to subside, and then between the sixtieth and the seventy-second hours it comes to an end. Towards this period the patient is very apt to show signs of exhaustion. His pulse becomes more and more rapid and feeble. His face, at first flushed, is now pale and haggard; his pupils are widely dilated; his tongue sometimes, but rarely, becomes dry and brown.

It is, however, precisely at this time that a favourable change is to be hoped for. Towards the end of the third night the patient commonly falls asleep. At first he is still uneasy and restless, his breathing is irregular, and after an hour or two he may wake up for a little while. He soon goes soundly to sleep again; his breathing is now slow and deep; a profuse sweat breaks out over his body. After six or eight hours he awakes and is relieved. In the next twenty-four or forty-eight hours he sleeps almost continuously, and after this his restoration to health appears complete.

In some cases, particularly in those who have previously been in good health, and in whom the attack has been the direct result of a debauch, the attack terminates earlier—perhaps at the end of twenty-four hours. In other cases it lasts beyond the specified time. Dr Ware speaks of having once known it to extend to nearly six entire days. This is most apt to occur in those who have for a long time been habitually intemperate.

But the end of the disease is by no means always favourable. Sometimes a sudden attack of convulsions occurs, by which the patient is carried off; sometimes he becomes comatose, and sometimes he falls back in his chair and dies unexpectedly in a state of syncope.

Delirium tremens has a marked tendency to attack the same patient over and over again, unless he makes an entire change in his habits.

Ætiology.—So far as is known, delirium tremens never occurs except as the result of alcoholic intemperance; but it is often exceedingly difficult to discover how intoxicating liquors are obtained. Women, in particular, will suborn their servants or attendants, or procure tincture of lavender or sweet spirits of nitre from the chemist, or drink eau de Cologne.

At one time it was generally believed that instead of the immediate exciting cause of delirium tremens being the alcoholic stimulus itself, the disease was most apt to occur in persons who, from whatever cause, had been suddenly deprived of the drink to which they had been accustomed. There can be no question that before the attack the patient has sometimes left off drinking for a few days; and, again, that it often shows itself in those who have been kept for a time without stimulants, in consequence of their having broken a limb or received some other injury. But many patients are attacked by delirium tremens as the direct result of a bout of hard drinking. And the experience of those who have the management of prisons and other institutions where abstinence is enforced, has demonstrated that this does

not in itself bring on an attack, even in the most intemperate. The facts which have been supposed to establish the contrary are otherwise explicable. First, a dislike for stimulants is sometimes an early symptom of the disease, so that the reason why the patient leaves off drinking may be that he is already beginning to suffer from its effects. Secondly, a sudden shock to the system is exceedingly apt to act as a direct exciting cause of delirium tremens in those who are predisposed to it by intemperance. It is this which renders the disease so common in the accident wards of hospitals. Indeed, it often comes on within the first few hours after the patient receives an injury, when there could have been no time for the withdrawal of stimulants to take effect. It is also frequently observed as a complication of acute pneumonia, erysipelas, or some other febrile disease in patients of intemperate habits.

Diagnosis.—As stated above, delirium tremens has been formally recognised only during the present century. Sutton, however, mentions that William Saunders, a former lecturer on medicine at Guy's Hospital, had forty years before (*i. e.* in 1773) described it as distinct from phrenitis.* Sutton had become acquainted with it when practising in East Kent, where spirits brought in by smugglers could be had in great abundance at a cheap rate. Certain of the practitioners in that district, he says, had learnt to treat such cases with opium; and this practice was attended with very marked success in comparison with that of others (including at first Sutton himself), who regarded the disease as an inflammation of the brain, to be combated by venesection, blisters, purging, &c. Sir Thomas Watson, in his classical work on medicine, approaches the subject entirely from this point of view. He speaks of once being summoned to a man who was supposed to be mad, or to have brain fever, and of the necessity that one should be alive to the distinctive symptoms of delirium tremens. But at the present day the opposite mistake is the more likely to be committed, a case being set down as one of this disease when it is really one of acute mania or acute melancholia, diseases which (it must not be forgotten) may also be the result of alcoholic intemperance.

Dr Wilks speaks of having seen general paralysis of the insane mistaken for delirium tremens on two different occasions by the same physician. In the surgical wards of a hospital there is often great difficulty in distinguishing the latter disease from the effects of injury to the head. Again, fever or acute pneumonia may be overlooked, and a case wrongly set down as one of delirium tremens, particularly if the patient should have been intemperate. But in such instances it is perhaps really present as a complication. Moreover, we must remember that pneumonia may be altogether latent in drunkards. Dr Wilks mentions rheumatic fever, when attended with cerebral symptoms, as particularly like delirium tremens in its superficial characters.

Treatment.—The observers who first distinguished delirium tremens from acute phrenitis obtained what seemed to them wonderfully successful results by treating it with opium, and until recently most writers have advocated

* This term, or its equivalents *encephalitis* and *meningitis*, was formerly used as the pathological explanation of delirium or mania with febrile symptoms. But it is now known that the clinical type of disease in question is associated with enteric or other specific fevers, with the hyperpyrexia of rheumatism or erysipelas, or with the toxic effects of alcohol; and in none of these disorders is there inflammation of the brain or its membranes. The symptoms of true meningitis are, as we have seen, very different, and there is no evidence that primary acute inflammation of the encephalon ever occurs.

this practice. Sir Thomas Watson, for example, recommends that three grains of solid opium should be administered as soon as the bowels have been cleared out by a moderate purgative; and that if at the end of two or three hours the patient should show no inclination to sleep, one grain should be given every hour afterwards until the result is attained. Or, he adds, corresponding quantities of laudanum, of Battley's liquor opii sedativus, or of morphia may be prescribed.

But this advice was based upon the supposition that the disease, instead of having a tendency to subside spontaneously, would run on, and perhaps prove fatal unless the patient were made to sleep. Sir Thomas Watson expressly remarks that delirium tremens is not likely to be "healed with a *placebo*, or by waiting upon nature." And it is clear that the physicians who laid such great stress upon the value of opium measured their success by comparison with cases of supposed meningitis or phrenitis treated by venesection, leeches, and blisters. Wilks, Anstie, and most modern writers endorse Dr Ware's statements as to the natural course of the disease.

It is still, however, a question whether the course of the disease may not be abbreviated by hypnotic medicines. Anstie thought that this might be effected by chloral hydrate. He gave thirty grains for the first dose, and repeated it in an hour if the patient did not sleep. He found that the patient almost always got two or three hours of sound repose, and sometimes much more. He was of opinion that in delirium tremens there is a tolerance for chloral, so that as much as ninety grains or even two drachms may be safely given in divided doses within twenty-four hours, at least for a day or two. But Dr Wilks is disposed to share Dr Ware's opinion that the duration of the disease cannot be shortened by giving medicines to send the patient to sleep. He thinks that a certain time is required for the subsidence of the commotion, and that a severe attack must last at least three days.

If this view is correct, it would seem to follow that at the commencement of delirium tremens neither opium nor morphia should be given at all, or at least that their administration should not be repeated so as to cause contraction of the pupils. For, when hypnotic remedies are actively pushed, one is apt to find oneself after two or three days in a difficult position. The patient, instead of sleeping, may be as excited as ever. His pupils are perhaps reduced to the size of pins' points, and he has had as much opium as would kill two or three healthy persons. Under such circumstances—which are precisely those in which a consultation is most likely to be sought—there can be no question that the proper course is to wait. The further administration of hypnotics is dangerous. Dr Wilks says that he has many times seen persons suffering from delirium tremens sent to their last sleep by opium, and the same result has followed the subcutaneous injection of morphia. The fatal symptoms produced by these drugs in patients suffering from delirium tremens seem to differ from those to which they give rise in healthy persons. At least a patient of the author's in these circumstances became collapsed rather than comatose. Indeed, as already mentioned, the disease sometimes terminates by sudden collapse, even when no hypnotics have been given.

Another question, which has sometimes been raised when a patient has died after the administration of a large dose of opium, is whether one can infer that this could not have been the cause of death from the fact that a certain interval of time had elapsed. Thus, in a case that occurred to Sir Thomas Watson, that physician decided that the medicine could not have

been concerned in bringing about the fatal result, because nine hours passed after the last dose (one of three grains) was given before the patient became comatose. This conclusion would be perfectly valid if the case were one of suspected poisoning in a healthy man, but it is scarcely equally safe in delirium tremens. Dr Christison long ago pointed out that in persons actually intoxicated with alcohol the effects of opium are much retarded.

But whatever doubts may fairly be entertained as to the part played by opium in bringing about a fatal result in cases of this kind, there can be none as to the importance of treating delirium tremens so that no such question can be raised. We have seen that most patients do well even if no opium at all is given, and therefore the fact that many recover after having taken heroic doses is no justification for administering them.

This, however, does not settle the problem whether or not it is advisable to give safe and moderate doses of opium in the early period of delirium tremens, at a time when there is no reason to suppose that the case will be one of so grave a kind. To determine that point, one requires to know whether the medicine, if it should fail to give sleep, can do any harm; and, again, whether it is ever needed at a later period, in order that one may not then be debarred from using it by having employed it at first.

Before we can decide the question we must know what is the class of subjects in whom delirium tremens is most apt to prove fatal. Now, as regards *prognosis*, Anstie speaks of old age as especially unfavourable, and one has been always accustomed to think that for young subjects the disease ought to be unattended with danger in a first attack, and even in two or three subsequent ones. Dr Aitken, however, quotes some statistical facts published by Dr Macpherson, and based upon observations made in the General Hospital at Calcutta, and it is remarkable that there the highest average mortality was in persons between twenty-five and thirty-five years old, being from 23 to 24 per cent. of those attacked, whereas the mean mortality at all ages was about 15 per cent. Among fifty-nine cases of fatal delirium tremens which have occurred within the last few years at Guy's Hospital, there were three in persons between twenty and twenty-nine years of age, eight in those between thirty and thirty-nine, ten in those between forty and forty-nine, eight in those between fifty and sixty. What ratios, however, existed between these numbers and those of all patients attacked by the disease during the corresponding periods is uncertain.

The state of the *kidneys* affects the prognosis in delirium tremens very materially, uræmic coma being very apt to occur as a complication. The urine must be repeatedly examined for albumen and for casts; and the quantity passed each day must be noted. If the secretion should begin to fail, Anstie recommends hot fomentations and dry cupping to the loins, hot foot-baths, and the administration of half-ounce doses of infusion of digitalis every three hours. Digitalis was recommended as a remedy for delirium tremens itself by the late Mr Jones, of Jersey, who used to give enormous doses of the tincture, and clearly showed that digitalis is one of the poisonous agents for which there is a special tolerance in this disease.

Of scarcely less importance in reference to the prognosis of delirium tremens is the state of the *heart*. Anstie pointed out that besides feeling the pulse, one should carefully watch the first sound of the heart with the stethoscope. And he laid still more stress upon the use of the sphygmograph. An "irregularly undulating" character of the pulse-wave—such as occurs in the typhoid condition—was found by him to be the most

unfavourable augury. In his article in the 'System of Medicine' a tracing is given which was taken from a man, aged forty, who, after being delirious for nearly a week, fell into a sound sleep of six or seven hours' duration, and when he woke appeared to be so much better that a confident opinion was expressed that he would recover. Anstie's sphygmographic observation, however, led him to augur the worst possible issue, and about twenty-four hours later the case terminated fatally.

The symptoms which indicate approaching failure of the heart's action are chiefly faintness and lividity of the countenance. Under these conditions free stimulation appears to be the only resource. If the stomach will retain ether, this may be given in half-drachm doses. But if not, Anstie recommends port wine, especially if it is old and contains volatile ethereal compounds in abundance. He speaks of giving an ounce and a half of such wine every hour. He also says that hot mustard plasters to the chest may be useful.

Before giving either opiates or stimulants it is most important to see that the bowels are freely open.

Dr Bristowe believes that opium may still be used even in full doses in delirium tremens with good results if given early and watched.

General management.—The liability for the heart to fail in delirium tremens renders it necessary that the patient should be well supported by nourishment from the very commencement of the disease. He may have milk if he will take it; but if not, he must be compelled to swallow strong beef-tea, beef-tea jelly, or soup. He may even have small pieces of underdone chop or steak, if he can be induced to eat them.

The administration of alcohol in moderate doses was formerly recommended in cases of delirium tremens as a routine practice; it was thought to aid in inducing sleep. But all those who have studied the natural course of the disease are now agreed that there is no proof of its acting in this way; and there are great objections to its use, since the patient's future depends entirely upon the effect which his illness may have in leading him to give up stimulants for the rest of his life.

Another matter of the highest importance is that the room should be kept cool and dark and quiet. The patient's friends, who commonly collect around him, must be sent away, one or two intelligent and able-bodied men being alone left to watch him. The gaslights are to be turned down, and in the daytime a dark cloth is to be hung before the window, unless the patient should be terrified by the hallucinations which visit him in the dark. If he should be very troublesome in wanting to get out of bed, the question must be entertained whether he should not be tied down. If an attendant can by persuasion, or by employing a little force from time to time, induce him to lie quietly in his bed, that is no doubt to be preferred. But it is far better that he should be kept in a recumbent position by a sheet folded across his chest and tucked well in, than that he should be violently held down and restrained for any length of time by the hands of those about him.

Chronic alcoholic neuroses.—Until recently the action of alcohol upon the nervous centres was commonly supposed to consist mainly in the production of the acute disease just described. But it is now known that a long-continued state of nervous disorder is of far more frequent occurrence.

Symptoms.—The most important of these neurotic symptoms is muscular tremor. This is more commonly noticed in the hands, which are unsteady

and shake; but Anstie found that in a majority of cases the lower limbs were really affected before the upper. The patient is often able at first to control the movements by an effort of the will. They are generally more troublesome in the morning than at any other part of the day, and they may render him unable to do any work requiring nicety of manual adjustment, until he has taken a dram, or eaten some food, by which for a time they are removed. Even before marked tremor occurs, the action of alcohol is sometimes manifested by a peculiar restlessness; the limbs are apt to start involuntarily, and cannot be kept quiet except by an effort of attention. At the same time there is an irritable condition of the mind; the patient, though he may feel drowsy when he goes to bed, cannot sleep, but keeps turning from side to side.

At a somewhat later stage other cerebral symptoms develop themselves. Anstie speaks of a buzzing or rushing sound in the ears as very common; and with it there is often a dull diffused headache. Muscæ volitantes are often complained of; flashes of light seem to pass before the eyes, especially at night, just when the patient is dropping off to sleep; and there are momentary attacks of vertigo.

The intellectual and moral powers gradually become impaired. All certainty of purpose is lost, and there is mental disquiet which makes it impossible for the patient to settle down to any occupation or to complete the tasks he may begin. He often has a vague feeling of dread for which he cannot account; or he may become the subject of some delusion, such as that an enemy is lying in wait to injure him. Anstie mentions as another symptom that the patient often has a vivid apprehension that he is in danger of falling down a precipice, even when walking on firm ground in broad daylight, and he says that this is of unfavourable augury.

Another occasional effect of chronic alcoholism consists in pains in the limbs, especially around the wrists and ankles, as well as in the shoulders and down the spine. They are somewhat paroxysmal in their character, returning each day at about the same hour, most commonly towards night; and they are greatly aggravated by fatigue, whether of mind or body.

Impairment of sensation is also apt to occur, especially in the upper limbs; and the power of muscular co-ordination may be lost, so that the state of the patient closely resembles that produced by tabes dorsalis. Epileptiform convulsions sometimes show themselves, and they are of the gravest augury. The mental state often passes into mania or melancholia, and ultimately complete dementia may develop itself.

Indications of gastric disorder are present at an early period. A common complaint is that of *nausea* in the early morning, or of actual vomiting, and this may recur day after day as regularly as during early pregnancy. Morning *diarrhœa* is another frequent symptom. There is generally a failure of appetite, particularly at breakfast-time. The tongue is foul, with a thick yellow fur; or, less frequently, it is red and glazed. Moreover, it is tremulous when put out. The breath acquires a peculiar fœtor, which is not that of any alcoholic drink, and which can hardly be described, although when once smelt it is unmistakable. The eyes are red and watery; the conjunctivæ are often slightly jaundiced; the features look flabby and expressionless; the nose, cheeks, and forehead are often reddened, with crimson points and lines, called *stigmata*, which correspond with minute dilated veins.

Sometimes the same parts of the face present a papular or pustular

eruption, such as is commonly known by the name of "acne rosacea," or the nose may be enlarged, with pendulous outgrowths. However, it must not be understood that the appearances last mentioned are seen only in those who have indulged in alcoholic excesses; they are sometimes seen in persons who have been perfectly temperate. Acne rosacea—or gutta rosea, as it is more properly termed—is in fact a symptom of dyspepsia, most often but not always the dyspepsia of drink. Moreover, in women it may be the result of disorder of the menstrual functions.

The limbs of a person suffering from chronic alcoholism are commonly wasted, especially the legs. The abdomen, on the other hand, is generally enlarged or pendulous, and its parietes, as well as the contained viscera, may be loaded with adipose tissue. In those whose chief beverage has been beer, even the limbs may be covered with fat; and since the interstitial connective tissue of the muscles is swollen by fat, there is often apparent bulkiness of the fleshy parts of the arms and legs.

With regard to the chronic action of alcohol upon the nervous centres Anstie remarks that, contrary to what is the case with the digestive organs, the effects depend almost solely upon the quantity imbibed, and not at all upon the form in which it is taken. There are, however, immense differences in the liability of different individuals to suffer from this poison. Some can drink spirits freely for years, and seem to be none the worse for it; others break down in health under comparatively small amounts of drink. Women in particular show little power of resisting its evil effects; perhaps because those who are intemperate commonly pass all their time indoors.

Among the *antecedents* of intemperance must be mentioned, in the first place, those occupations in which persons are brought continually into contact with intoxicating liquors. A large proportion of the patients who present symptoms such as have been described are men employed in breweries or distilleries, public-house keepers and their wives, and travellers for wine and spirit merchants. Cab-drivers and hawkers, and others who are exposed to rough weather, are also very apt to be intemperate; while for some persons, as cooks and shoemakers, it is admitted as an excuse that their occupation is monotonous, deprives them of proper exercise, and keeps them confined in close, ill-ventilated rooms. Depressing mental influences drive others to drink; poverty and despair make them eager for the oblivion of intoxication. Again, there are cases in which stimulants were at first taken for the relief of pain, but in which the habit of indulgence grows upon the patient until it becomes a disease. Anstie has rightly laid great stress on the responsibility of allowing women to take wine or brandy in order to render them less susceptible to neuralgia, or to the sufferings which are so apt to attend on the menstrual period.

Lastly, there is no doubt that proclivity to intemperance is capable of hereditary transmission. This tendency is by some writers regarded as itself a neurosis, to which they give the name suggested by Roesch, "Oinomania," more correctly "Œnomania." The patient is seized every few months with a craving for drink, and for days together he behaves like a madman, taking long journeys without any purpose, or perhaps behaving indecently, eating little and drinking much. But when the affection passes off—at the end of a month or so—he regains his usual health. He then lives soberly and chastely, and manages his affairs with intelligence.

The *morbid changes* that are found in the nervous centres of drunkards are essentially atrophic. The cerebral convolutions are wasted, and the

cerebro-spinal fluid between them is in excess. The arachnoid is opaque and thickened. Even the bones of the cranium are sometimes found denser than normal and without diploë.

The effects of chronic alcoholic poisoning in producing certain forms of spinal paraplegia and the still more characteristic paraplegia due to peripheral neuritis have been already discussed (pp. 423 and 458).

The *diagnosis* of chronic alcoholism may present every degree of difficulty or it may be perfectly easy. Commencing general paralysis, locomotor ataxia, hysteria, and the nervous malaise which may result from dyspepsia, are perhaps the conditions most likely to be confounded with it. Unfortunately one cannot place any confidence in the statements of the patient himself, however guardedly our questions may be put, for persons who indulge in secret drinking are always untruthful. Anstie recommends that one should abruptly but not uncourteously hazard the observation that the diet must be strictly unstimulating; this, he says, will often cause the patient to betray the truth by his manner, or his air of surprised unconcern may prove that the suspicion is groundless.

In the *treatment* of chronic alcoholism the most important point is that the patient should abstain at once and entirely from all intoxicating drinks. It is in such cases above all others that large hydropathic hotels are of service, where regular habits and exercise in the open air are enforced, while an unstimulating diet is provided and all facilities for procuring drink are withdrawn.

The administration of certain medicines may also be of considerable service. Anstie recommends especially quinine, which (if there should be sickness) may be given in a state of effervescence. Dr Marcet's favourite remedy was the oxide of zinc; he says that in doses of from two grains upwards thrice daily it has a powerful effect in inducing sleep. Bromide of potassium often does great good in cases of this kind. To relieve the imperious craving for drink, aromatic spirits of ammonia, tincture of nux vomica and tincture of capsicum in a bitter infusion are extremely useful drugs. According to Anstie, half-drachm doses of ether with the same quantity of tincture of sumbul may do much to restore tranquillity to the nervous system and to make sleep possible. As a more direct hypnotic he recommends from a quarter to half a grain of the extract of Indian hemp. Chloral hydrate and hyoscyamus are also valuable hypnotics. If opiates are absolutely necessary, one should always employ the hypodermic injection of morphia (from one tenth to a quarter of a grain) rather than give any preparation of opium by the mouth, and this only when the urine is free from albumen and the patient has been purged. Even in advanced stages Anstie obtained striking benefit from the administration of cod-liver oil; and he says that when there is much tremor, strychnia is often useful in a dose of $\frac{1}{48}$ to $\frac{1}{32}$ of a grain three times daily.

As to *prognosis*, the symptoms of chronic alcoholism may last for years; and even the hardest drinkers sometimes reach old age. They are indeed apt to become prematurely old, their hair turning grey and their arteries becoming rigid. Gout, chronic disease of the kidneys or liver, or fatty degeneration of the heart may be developed, and cerebral apoplexy may cut them suddenly off. Such diseases as pneumonia or fever are ill borne, and are very likely to prove rapidly fatal, as are also accidental injuries and surgical operations.

NEUROSES FROM MORPHIA.—The evil which arises from the abuse of that invaluable drug, opium, has long been recognised. It is taken as a valuable medicine in malarial districts—in Cambridgeshire, for instance; and probably its abuse began in the same way in China. It produces loss of appetite, constipation, and emaciation, with the deterioration of the character which always follows indulgence in what is known to be an evil habit. Coleridge, after many years of uselessness and misery, emancipated himself from the thraldom. De Quincey has left in his 'Confessions of an Opium-eater' a monument of the pleasures, the pains, and (it must be added) of the incapacity to tell the truth which this habit produces.

Opium-smoking as practised among the Chinese is said to be even more injurious than opium-eating.

The useful and convenient practice of subcutaneous injection of morphia has of late years brought with it, in Western Europe and in America, a more wide-spread abuse than that of opium. The morphia-habit, as it has been termed, seems to be more prevalent in Germany than in England. It usually begins in the legitimate use of the anodyne to relieve pain, but the result is so rapid and effectual that the patient is apt to make the punctures himself, and, once familiar with the practice, he continues it long after the original disorder for which it was prescribed has disappeared.

The patient suffers terribly from insomnia and restlessness, he (or she) loses appetite and becomes pale and sallow, sometimes constipated and sometimes troubled with frequent and irritable action of the bowels. Moreover, sooner or later some of the punctures are sure to suppurate, and the pain of the abscess leads to fresh injections in parts before spared.

The writer has only seen a few cases of this malady. The first was an old gentleman from America, who had long become accustomed to the habit and suffered comparatively little. The next was an elderly lady, who had begun the practice for facial neuralgia and succeeded in breaking it off. The third was a young American, who suffered from obscure pains in the region of the gall-bladder. A fourth was a maiden lady, who began the habit to allay the pain of a renal calculus, and who was cured of both at last. In a fifth case, where the arms were scarred all over with the marks of abscesses, abdominal pain had been the origin. A sixth occurred in a young man, the subject of severe and complicated caries of the bones and joints, and he more than once nearly killed himself with a large dose.

The prognosis is not worse than in cases of alcoholic intemperance. The patient must be encouraged to bear the pain, and when unsupportable it must be relieved by smaller doses of the remedy. Often a single drop of the officinal solution is sufficient, and not infrequently pure water has, by a pious fraud, been substituted for the liquor morphiæ. Moreover, bromides, chloral hydrate, hyoscine, sulphonal, or chloralamide may each be substituted with advantage in its turn.

Neuroses from other drugs.—The *bromides* themselves produce, if long given in large doses, very unfavourable effects on the intelligence, of which an example which came under the writer's care is mentioned at p. 766.

Chloral hydrate produces a still more miserable condition of depression in some patients, and, valuable as it is, should never be used as an habitual medicine.

HYSTERIA AND HYPOCHONDRIASIS

"Orandum est ut sit mens sana in corpore sano."
JUVENAL.

"In nervous diseases he is the best physician who knows best how to inspire hope."
COLERIDGE.

HYSTERIA—*A real and distinct disease—Mental and moral perversions—Hysterical affections of sensation and of movement—Contractures—Globus hystericus—Flatulence—The hysterical fit—Ætiology and Pathology of hysteria—Diagnosis—Prophylaxis—Treatment.*

Catalepsy—Trance—Sleep-walking—Ecstasy—Dancing-convulsions—Mania—Hystero-epilepsy—Anorexia and marasmus—Hysteria in men and boys.

HYPOCHONDRIASIS—*Distinctions from hysteria—The supposition of imaginary diseases, commonly abdominal—Distinction from melancholia—May mask real disease—Treatment—Prognosis.*

HYSTERICAL disorders of function, or pains, or perverted sensations, are seated in the most diverse organs of the body, not only in the head, chest, and abdomen, but also in the joints, the mammæ, the eyes, and the limbs.

But is hysteria a distinct and definite malady? For there are some who refuse to admit its claim.

The name* suggests the erroneous opinion that the organs of generation in the female play the principal part in causing hysterical affections. Those who see little or no connection between them have been tempted not only to do away with the name, but to dispute the clinical association of the symptoms as manifestations of a single malady.

Again, it must be admitted that, more than most other diseases, hysteria is difficult to define. As a neurosis, independent of any appreciable structural change, its definition would naturally be based upon either its causes or its symptoms. But the former are still the subject of discussion, and the latter are singularly variable and inconstant. Moreover, the curability of most hysterical affections, and the fact that they are generally contrasted with organic diseases, have caused a tendency to apply the term vaguely to cases of unascertained nature, but which are regarded as of a trifling character, and likely to be of transient duration. In this way the words hysteria and hysterical have often become meaningless.

Very little study at the bedside, however, is needed to convince one that most of the affections called hysterical are really the expression of a special morbid condition, for which the name of Hysteria is as convenient as any other, besides having the sanction of antiquity and established usage. One finds that two or more of these affections are commonly present in the same patient at the same time, or that a person who has suffered from one is

* Ὑστερία (*i.e.* womb-sickness), from ὑστέρα, the uterus—Passio hysterica.—*Anglicè*, Fits of the mother—The vapours.

exceedingly apt to be afterwards attacked by others. Then, again, there are marked peculiarities in the age, sex, disposition, and other conditions of such patients. Above all, there is in most cases a particular mental state which can easily be recognised apart from other indications of the disease, and which may be regarded as its fundamental character.

Mental condition.—The principal features of the mental state which characterises hysteria are an exaltation of the emotions, a perversion of the will, and a loss of the balancing power of the judgment. The patient seems to have no power of controlling her own feelings. The most trifling occurrences excite her to rapture or plunge her in despair. She may conceive a violent affection for some persons, and an equally irrational aversion from others. She perhaps exhibits great attachment to some pet animal, while other creatures, no less harmless, excite in her repugnance and disgust. She torments all those about her with her caprice and her selfish claims upon their attention; she appears unable to make up her mind to the smallest effort, and lies in bed all day from sheer want of energy to rise. But in some particular direction she will show the most obstinate determination and tenacity of purpose. She has a great craving for sympathy, and is exceedingly anxious for her delicacy of health to be recognised. In pursuance of this object she will apply corrosive acids to her skin, swallow needles day after day, or run them into all parts of her body, and make unsuccessful attempts to poison or drown or hang herself. Her stoical endurance of pain is sufficient to show that a mere defect of volitional power cannot be the essential element of hysteria. Perhaps the best way of expressing the facts is to say with Dr Reynolds ('Syst. of Med.,' vol. ii) that the will is no longer called into exercise by the judgment or reasoning faculties, but only by some one dominant idea or emotion. Thus, as Jolly observes (von Ziemssen's 'Handbuch,' vol. xii), if one can by stimulating her enthusiasm or spirit of emulation supply a hysterical patient with a sufficient motive to undertake any good work, such as nursing, she will often carry it out with more than ordinary perseverance and energy.

Moral perversion.—The moral tone of a hysterical woman is often seriously impaired, particularly in certain directions. Morbid sexual inclinations have often a strong hold upon such a patient, and she will scheme to induce her medical attendant to make a vaginal examination. Sir Thomas Watson relates a case in which a young woman contrived to make a hospital surgeon believe that she had a stone in the bladder; and the imposture was not detected until she had been tied up in the position for lithotomy in an operating theatre full of students. A patient who was supposed to have a hydatid in the liver, and who had been punctured without result, allowed the operation to be repeated, and almost immediately produced a piece of the stomach of a rabbit (or some other small animal), which she declared she had vomited, and which she no doubt thought would be mistaken for a hydatid membrane; a few hours later she sent for her medical man again, to remove from her vagina another piece of the same substance. Others have been known to drink their urine and then to bring it up again, pretending that none was passed in the natural way. The fact that such cases have occurred makes one hesitate to accept as authentic such cases as have been described on the authority of Charcot as hysterical ischuria. There is often great difficulty in detecting impostures of this kind. Charcot himself relates a case of Boyer's in which a woman pretended that urine came from her umbilicus, ears, eyes, and breasts, and that she vomited

fæces; and it was not until she had been placed in a strait waistcoat that little balls of fæces ready prepared for swallowing were found in her bed. Hysterical young women also simulate phthisis and pretend to spit or vomit blood.*

Some of the *factitious affections of the skin* are by no means easy of diagnosis. In the museum of Guy's Hospital there is a model of the right breast of a girl, which is reddened and has on it a number of large raised tubercles, some of them bigger than peas. The first time that patient was an inmate of the hospital the cause of the affection remained undiscovered, although it was evident that some irritant was being intentionally applied. But more than a year afterwards she was again admitted, and Mr Birkett, happening to visit the ward at an unusual hour, found a piece of lint, strewn with powdered cantharides, which she had put on the breast. Sir William Gull related a similar case in which he detected with a lens a glistening fragment of the same powder on the skin itself. Some years ago a girl was admitted into Miriam Ward who had on her chest and breasts a number of whitish gangrenous-looking patches, of irregular sizes and forms; these successively shrivelled up into brownish scabs, which soon became detached, leaving the skin beneath reddened and rather scaly. On one finger, in the groove between the skin and the nail, there was found a bright yellow stain, which affected both structures to about the same extent, and which seemed indisputably to have been caused by a drop of nitric acid. So that perhaps the patches on her chest were likewise produced by the acid, although they did not show the characteristic yellow colour. It happened strangely enough that shortly before she came in there was in the ward another patient affected in exactly the same way, but (there was no reason to doubt) with spontaneous gangrene. She also was a girl, aged eighteen, but apparently free from suspicion. The museum contains models taken from each of these patients.

Other forms in which hysterical patients exhibit their craving for notoriety and their willingness to deceive are illustrated by the cases of the Welsh fasting girl, and Louise Lateau, the Belgian nun.

Physical symptoms.—Among the manifestations of hysteria "the hysterical fit" has always been regarded as especially typical of the disease; and two others, the "globus" and flatulent distension of the abdomen, are more common and scarcely less distinctive. Before describing them, however, it will be convenient to mention some symptoms which are less often seen.

Perversions of sensation.—Not the least curious of these are perversions of the special senses. The patient perhaps complains of intolerance of light, and insists on having the room kept darkened. Here, however, imagination often plays a great part. Dr Reynolds relates the case of a woman who had for weeks been lying with her hands before her eyes to keep out the light of a dull London sky. When he brought a candle close to her in order to examine the pupils she shuddered, knit her brows, and held both hands between it and her eyes. But as soon as her attention was distracted to the state of her front teeth, the brows became relaxed, the hands were removed, and she bore the light without inconvenience. In other cases the patient is distressed by the slightest sound, and will allow no one to speak above a whisper. Yet such a person may herself exclaim in a loud voice or

* A remarkable case of this kind obtained some notoriety about thirty-five years ago by the publication of a book called 'The Female Jesuit in the Family.' The patient, a typically hysterical governess, imposed on the Protestant credulity of the household.

make a great noise in stirring the fire without seeming to mind it. In other cases there appears to be an actual exaltation of perception. A hysterical girl may seem, as Dr Reynolds says, "to hear through stone walls;" but in such matters deception is often practised, for such a patient often pretends that she can see with her eyes shut.

Jolly quotes from Amman the case of a woman who discovered the presence of some cherries in another room by their odour, and who could distinguish one person from another with her nose; and such persons often detect by their taste the presence of the minutest trace of any flavour that they dislike. It is perhaps a perversion of the gustatory sense that leads girls affected with hysteria to eat cinders, sealing-wax, lead pencil, and the like; this perverted appetite used to be called "*pica*." They are sometimes equally fond of repulsive odours or flavours.

The sense of touch, again, may be unduly acute. In almost every case of hysteria there is at some part or other of the body over-sensitiveness to painful impressions—*hyperæsthesia*, or rather, in strict language, *hyperalgesia*. Sometimes the patient complains that it hurts her very much to have the skin over one or more of the spinous processes pressed upon or even touched; sometimes she has extreme tenderness of the breast, or of the edge of the costal cartilages.

Another frequent effect of hysteria is impairment of common sensation, *dysæsthesia* or *anæsthesia*. This may either be limited to ordinary tactile impressions or it may include those of heat and cold; in other instances it concerns only the perception of pain, and is called *analgesia*. Gendrin went so far as to declare that sensation was more or less defective in every case; and other writers have asserted that loss of feeling in some part of the skin is invariably left behind by hysterical fits. Their statements, indeed, are too absolute, but the symptom is undoubtedly often present, and Lasègue and Charcot are probably right in saying that it would be more frequently observed if it were carefully looked for, since the patient may be unaware that she is unable to feel pain in some particular part, until her sensibility is tested. In many cases, however, subjective sensations of tingling, pins and needles, &c., are experienced and complained of by the patient. It is important to note that there is no opposition between hyperæsthesia and anæsthesia, such as might appear from the names. A part of the skin may be exquisitely tender, and the seat of burning pain when touched; and yet at this very part the power of appreciating tactile impressions may be greatly impaired.

Anæsthesia, or defective sensation, is much more frequently observed in some regions than in others; Jolly mentions the backs of the hands and feet, and the parts above the outer malleoli, as its favourite seat. Sometimes it affects exactly one half of the body, leaving the other free. To such cases Charcot has given the name *Hemianæsthesia*. He quotes Briquet as having stated that this occurs on the left side more often than on the right side in the proportion of seventy cases to twenty. The limitation of the parts in which there is loss of feeling is often remarkably sharp, corresponding almost precisely with the median line of the face, neck, and body. It differs from hemiplegia in this character and by the greater implication of sensation than of motion. The mucous membranes are affected in a similar way. Taste may be wanting in one half of the tongue, the sense of smell may be impaired, and there may be a considerable degree of amblyopia, with limitations of the visual field for the several colours—a

symptom which Galezowski calls *Achromatopsia*. According to Jolly, reflex excitability is also wanting; sneezing cannot be induced by irritating the nose, nor retching by tickling the fauces on the affected side. Lastly, Charcot says that the side on which sensation is impaired is cold and pale, and that there may be difficulty in drawing blood from the skin by a needle's prick.

Altogether apart from hemianæsthesia, loss of feeling in the mucous membranes is common. Anstie laid considerable stress on the frequency with which it may be found, if looked for, in the back of the pharynx. According to that writer ('Lancet,' ii, 1872), whenever a person who has not been taking a bromide can without retching let one pass the finger down to the epiglottis, the diagnosis of hysteria is probably correct. Dr Reynolds mentions that he has known several cases, occurring in married women who were still bearing children, in which there was absolute anæsthesia of the vulva and vagina. Impairment of sensation in the bladder is supposed to be sometimes the cause of retention of urine in hysterical patients, but in other cases it appears to be due to a prurient desire to have a catheter introduced. Jolly relates the case of a hysterical patient who burnt herself terribly by taking live coals out of the fire and pressing them with both hands into her vagina, without showing any sign of pain.

Hysterical anæsthesia is probably never permanent. It may last for several weeks and even for months, but sooner or later it always passes off.

Motor paralysis.—Another manifestation of hysteria is paralysis of movement. Aphonia and dysphagia often result from hysterical loss of power in the laryngeal and the pharyngeal muscles respectively; and the former is highly characteristic, so that its presence gives great aid towards the diagnosis of doubtful cases. Not uncommonly hysterical paralysis takes the shape of paraplegia or of hemiplegia. The former affection was described at p. 462. The latter likewise presents characters of its own. It occurs much more frequently on the left side than on the right. The proportion in Briquet's cases was as forty-six to fourteen. An important distinction between it and the paralysis due to a lesion in the opposite side of the brain is that in hysterical hemiplegia the side of the face and tongue remain unaffected. This was long ago remarked by Dr Todd, who also pointed out that the patient in attempting to walk "drags the palsied limb after her, as if it were a piece of inanimate matter, and uses no art of circumduction nor effort of any kind to lift it from the ground; the foot sweeps the ground as she walks." Dr Reynolds adds that a paralytic patient looks at her feet; a hysterical patient at the persons who are watching her.

In some cases one limb is alone affected with hysterical paralysis; or, much more rarely, only part of a limb. The only muscle affected singly is the levator palpebræ; and hysterical ptosis is not uncommon.

Hysterical paralysis may be transitory, lasting only a few days, or not longer than a few hours. Sometimes it afterwards reappears either in the same limbs or in others. But there are cases in which it persists for months or even years; and in some cases rigidity sets in, to be mentioned in the next paragraph. The paralysis may disappear suddenly, under the influence of a sudden emotion or shock; or it may pass off very gradually. The removal of the patient to a hospital ward—away from sympathising friends and relations—is often followed by a more or less rapid recovery. In several cases under Dr Wilks's care this result has been brought about rather by moral influence than by any special treatment. The patient is told

that she is expected to begin to move the paralysed limbs; day by day she is encouraged to do more; after a time she is taken out of bed, dressed, and put into a chair; and before long she walks as well as ever.

Contractions.—Another and a very curious effect of hysteria is a chronic spasm or rigidity of one or more of the limbs, associated with a complete loss of voluntary movement. This has recently been studied with much care by Charcot, who has published in his 'Leçons' several capital drawings illustrative of the distortions which it produces. Some English writers have since adopted into our language the French word *contracture* for such cases. The affection often follows immediately upon a severe hysterical fit; and the paralysis and the rigidity then generally develop simultaneously. But in some cases the latter does not come on until there has been loss of power for a considerable time. In certain cases only one leg or one arm becomes contracted; but sometimes both legs are affected, sometimes both the arm and the leg on one side, sometimes three of the limbs, or even all four. When the affection assumes a hemiplegic type, and the rigidity follows the loss of power after some interval, it might be thought that there would be a difficulty in distinguishing it from the "late rigidity" of hemiplegia due to organic disease of the brain (p. 567); but in the hysterical affection the contraction comes on, not gradually, but suddenly, and as the immediate result of a fresh hysterical fit. Moreover, the positions assumed by the individual limbs are peculiar. The arm is semiflexed; but, according to Charcot, the leg always falls into a state of rigid extension, the knee and ankle being straightened and the toes stretched down to the utmost extent possible, while the sole is turned inwards. Thus the condition of the foot resembles that which exists in talipes equino-varus. Charcot also mentions that the adductors of the thighs are forcibly contracted; and Jolly relates a case in which one leg became powerfully flexed, especially at the knee-joint. In a marked case of hysterical paraplegia (which came under the writer's observation many years ago) the girl's legs were forcibly flexed at the knees and hips, so as to resist the utmost power that could be safely used to straighten them, until chloroform was administered. She afterwards recovered completely, and became an excellent nurse.

The rigidity in these cases is not relaxed during sleep; nor does it undergo any variations in degree at different times or periods of the day. The spasm is by no means confined to a single set of muscles, for one is not able to force the patient's arm (which is semiflexed) into a position of complete flexion, any more than to extend it. By making the patient inhale chloroform, however, if its action is carried far enough, one can temporarily remove the spasm, the affected parts becoming perfectly supple in all but very exceptional cases.

Anæsthesia of the affected limbs is generally present. The muscles remain well nourished, and retain their electro-contractility at least for a considerable time. But when a limb has been contracted for some years without intermission, a little general wasting may occur, and the reaction of the muscles to galvanism may be somewhat impaired. The termination of hysterical "contracture" is almost always in recovery; and in many cases this takes place abruptly. One of Charcot's cases is very instructive. A woman was first attacked, at the age of thirty-four, with loss of consciousness after a moral shock; she then fell into the fire and burnt her face severely. After this she had several seizures, some of them hysterical in

character, others rather epileptiform. Four years afterwards she had a very severe fit, attended with convulsions and followed by an apoplectiform stupor with stertorous breathing; this was at once followed by left hemiplegia. Rigidity of the left limbs set in abruptly after an interval. In the following year the right limbs also became contracted; and later still the jaws were fixed, so that an œsophageal tube had to be used. Her right arm, however, became free; and Charcot maintained that recovery was still possible. One evening, six years from the commencement of the contraction of the left arm and leg, she had an attack in which she imagined herself to be about to die. She cried out, became agitated, and with her right arm pushed aside those who held her. Her strong desire to get to the window for air was resisted; she became more and more angry; and first her right leg lost its rigidity, then her left leg, and finally her left arm. She got up and walked; and in eight hours her cure was complete. A slight crackling in the joints was all that remained of the complaint.

Such a case has an obvious bearing upon those in which cures are attributed to miraculous agencies. They are seldom related in such a way as to enable one to speak positively as to the exact form of paralysis which had been present. But Charcot quotes an article by Littré in which detailed histories are given of certain persons who were cured at the end of the thirteenth century by pilgrimages to the tomb of St Denis, where the relics of Louis IX had recently been deposited. Three of these were young women who had been suddenly attacked with contraction of one leg or of the arm and leg on one side, and who also had anæsthesia. They were cured suddenly, under circumstances certainly very likely to act upon the imagination. In fact, the analogy seems to be complete.

In some exceptional cases of hysterical "contracture," however, recovery never takes place. Charcot mentions several instances which he believed to be hopeless. One is that of a woman, aged fifty-five, whose legs had been contracted for sixteen years. Under chloroform her knees could still be relaxed; but her feet remained in a condition of equino-varus. This observer has made an autopsy in one case in which all four limbs had been contracted for ten years; and he discovered sclerosis of the lateral columns in nearly the whole length of the cord. The patient was a hysterical woman, and the rigidity passed off several times and returned again before it became permanent. There seems no reason to doubt that the case originally belonged to the same class as the rest. Charcot accordingly supposes that sclerosis may come on secondarily in such cases. The points on which he would lay stress as indicating the probability of an unfavourable termination to a case of long-standing contraction of a limb are that particular groups of muscles are wasted in an extreme degree and affected with fibrillary tremor like what is seen in progressive muscular atrophy; that there is a great diminution in the contractility, as tested by faradisation; and that the rigidity should remain to a very considerable extent when the patient is under the influence of chloroform. On the other hand, he does not attach any importance to a little general loss of substance in the affected limbs, to a slight impairment of the electrical reaction of the muscles, or to the presence of spasmodic movements, which last are not uncommon in such cases, as in those of ordinary hemiplegia.

Globus.—Among the most common and characteristic symptoms of hysteria is the so-called *globus hystericus*. It is difficult to say whether it is merely a morbid sensation, or depends upon spasmodic contraction in the

œsophagus and pharynx. The former opinion has been maintained by Eulenburg and Reynolds, the latter by Jolly. To the patient herself the globus is a sensation, most commonly a feeling as if there were a ball or lump in the throat, which she cannot swallow or get rid of in any other way. She may even put her finger into the pharynx, and make herself sick, although she knows there is not really anything that can be dislodged; or she may drink mouthful after mouthful of water to wash it down. The exact nature of the sensation varies a good deal in different persons. In some it is likened to that which would be caused by a bean sticking in the throat; others feel as if a worm or some other living animal were creeping about in its interior. With others, again, it is rather a feeling of constriction about the neck as if the collar was too tightly fastened. The relation of such a feeling to the state of emotional excitability which characterises hysteria is shown by the fact that a precisely similar sensation is felt by healthy persons when suddenly seized with grief or terror. Thus, children before a fit of crying experience a sensation of a lump in the throat which is probably identical with the more marked form of globus. In some hysterical women the lump is not merely felt in the throat, but seems to rise up from the chest, or from the abdomen.*

Flatulence.—Another frequent symptom of hysteria is a rapid distension of the intestines with gas. The abdomen may suddenly swell up, so that the patient is obliged to take off her stays and undo all the fastenings round her waist. Jolly remarks that this form of tympanites bears no relation to meals. In several instances he has seen it return each morning regularly and attain its maximum about midday. The gas may ultimately escape either by the mouth or from the rectum. Jolly says that it is commonly quite free from odour; and this, he adds, explains the fact that the distension sometimes subsides without any apparent escape of wind in either direction. How such an enormous quantity of gas can be produced in the stomach and bowels is quite unknown. It is sometimes undoubtedly air which has been swallowed; sometimes probably gases, liberated from the food and expanded in accordance with physical laws by relaxation of the muscular walls of the stomach and bowels. The chemical character of the gas needs more exact determination, but it is believed to consist chiefly of carburetted hydrogen.

In some cases hysterical tympanites persists for years together, the abdomen being as tense as a drum. Bamberger alludes to a case of this kind, in which the patient passed through an attack of cholera without alteration in the size of the abdomen, but in which an abundant flow of saliva, coming on spontaneously, once led to its temporary subsidence.

The hysterical fit.—There remains to be described that which was once regarded as the chief symptom of hysteria, the hysterical attack or "fit of the mother." In the majority of cases no such attacks occur during any part of their course; according to Briquet, in three cases out of four. Moreover, when they do occur they present great variety of symptoms. Sometimes they are of so trifling a character that it is unnecessary to send for medical advice. The patient perhaps has an unusually painful globus, and then begins to cry and sob, or falls into violent laughter. Or she may laugh and cry alternately, until she is exhausted. Such an attack, for which the vernacular name is now "hysterics" and was formerly "vapours," may occur singly, or there may be several in the course of two or three days.

* So Lear:—

"Down, climbing sorrow: thine element is below."

A very constant symptom is that when they pass off the patient voids a large quantity of colourless urine, of low specific gravity.

In many cases a hysterical attack is accompanied by violent movements of the body and limbs which may be distinctly convulsive in character. Perhaps the patient screams out, and then fall into a state of opisthotonos, remaining supported for some minutes together only by the back of her head and by her heels. Or she may throw her limbs in all directions, beating them on the ground, or striking her own chest with her closed fists, tearing her hair, kicking those about her, and struggling with all her might to release herself from restraint. Or, again, she may thrust one arm high in the air; or forcibly bend her arm over the chest, and her thighs across one another; some of the fingers and toes being at the same time stretched apart to the furthest possible extent, while others are as strongly flexed. The respiration is much quickened, and it may be very noisy, but it is not actually stertorous. Her features undergo the strangest contortions and grimaces. Her eyes are generally closed; the pupils are of natural size. The eyelids quiver, and the eyes are often turned upwards, particularly if an attempt is made to separate the lids by force. The state of the eyes thus differs altogether from that which belongs to an epileptic fit, for in it they are commonly fixed wide open, and have their pupils greatly dilated.

There appear to be all degrees of impairment of consciousness in hysterical attacks. At the commencement the patient almost always knows what is happening, so that she is able to place herself out of the way of injury. Sometimes she keeps on screaming during the greater part of the fit, or shouts out "fire," "thieves" or "murder," or pours forth a continuous current of the foulest language. Sometimes she has visual hallucinations, addressing furious objurgations to imaginary persons, or fancying that she is surrounded by wild beasts or spectres. Sometimes she seems to be altogether unconscious; but even then by careful watching one may often make out that she really notices what is going on, casting occasional furtive glances at the bystanders from between the half-closed eyelids or modifying her behaviour under the influence of their remarks.

Ætiology.—In passing on to consider the causes of hysteria, we find ourselves face to face with a question which even now can hardly be said to be settled, although it has been discussed for centuries—the question as to the part played by affections of the generative organs in the ætiology of the disease. The very name *hysteria* involves etymologically the doctrine that it is the result of uterine disorder; and the ancient Greek writers—including Plato and Aristotle—actually supposed that the womb left its place in the pelvis and wandered about the body, setting up disturbances in different parts. From their time to the present there have never been wanting theories which, according to the different standpoints afforded by the science of the age, have referred hysteria to a similar cause. The physicians who have held such views in extreme forms have, indeed, been generally professed gynæcologists rather than men acquainted with the pathology of nervous diseases; but Romberg, the great German authority on these disorders forty years ago, defined hysteria as "the reflex neurosis proceeding from sexual irritation."

By different writers various disorders of the female sexual apparatus have been made the starting-point of hysteria. Some have endeavoured to trace it to unsatisfied desire, citing in support of their views the frequency of its occurrence in young widows and in the wives of impotent husbands;

others have referred it to masturbation or to excessive venereal indulgence, and others again to the common menstrual disorders. Addison published a clinical lecture in 1830 to show that its phenomena depended upon "uterine irritation." By Dr Henry Bennet ulceration and induration of the cervix uteri were represented to be morbid conditions of great potency in causing such effects. More recently Dr Graily Hewitt has assigned the principal place to flexions of the womb.

Charcot has laid great stress on the frequency with which hyperæsthesia of the ovary is present. When lecturing on this subject at the Salpêtrière he showed to his class five women (almost all the hysterical patients who were then in the hospital), each of whom had pain in, or tenderness on pressure over, one or both of the ovaries. According to him the pain is sometimes very acute, and widely diffused over the abdominal surface, with special hyperæsthesia of the skin over an area two or three inches in diameter, corresponding with adjoining parts of one iliac and of the hypogastric regions. In other cases no spontaneous pain manifests itself; indeed, the skin is anæsthetic, and the muscles can be pinched up without pain; but on making deep pressure towards the brim of the pelvis one can feel the ovary as an egg-shaped body, which slips beneath the fingers. Further pressure upon it gives rise, not exactly to pain, but to a peculiar sensation which the patient at once recognises, having felt it many times before as the starting-point of hysterical attacks; and this, passing up to the epigastrium, is followed by pain in that neighbourhood, and sometimes by nausea and vomiting. Next, if the pressure on the ovary be continued, the patient experiences palpitation of the heart with extreme rapidity of the pulse, a sensation of globus in the neck, a hissing noise in the ear of the same side, a feeling as if blows were being struck with a hammer on the temporal region, an impairment of vision, especially in the corresponding eye, and then perturbation of consciousness, ending in a regular hysterical fit. Charcot also says that when there is hemianæsthesia, or paralysis, or contraction of the limbs on one side of the body, it is always the ovary on the same side which is hyperæsthetic; and that if such symptoms are bilateral, both ovaries are affected. Lastly, he has found that when a patient is seized with a hysterical attack, even if it is epileptiform, it may be cut short by energetic compression of the ovary continued for three or four minutes.

Charcot, although he speaks of ovarian hyperæsthesia as "playing a predominant part" in the clinical history, nowhere speaks of it as the *cause* of the disease. There are, in fact, ample proofs that Romberg's definition, already quoted, is inaccurate. Thus hysteria is occasionally met with in males, according to Briquet in as many as 5 per cent. of all cases; and Dr Reynolds says that in them its development seldom bears any relation to the generative functions; he has sometimes observed it in boys at puberty, but the most marked cases which he has seen have been in men from thirty-five to fifty or upwards, who have been mentally overworked or greatly reduced in physical power. So, also, in women, although probably more than one half of those who become affected with hysteria show the earliest indications of it between the twelfth and the twentieth years, about the time when menstruation was first being established, there are yet a considerable number of girls who manifest hysterical symptoms at a much earlier period of life. No fewer than one in five of Briquet's cases occurred in girls under the age of puberty.

It is one of the most important facts in the ætiology of hysteria that,

even among children, it is far more common in girls than in boys. We have seen (p. 738) that this is the case with chorea likewise, and in both diseases the preponderance of cases in females is probably due to the same cause, namely, their innate emotional susceptibility and want of power to resist external influences. It has been correctly remarked that hysteria seldom, if ever, shows itself in such women as would be called "masculine," whereas the men and boys who are attacked by it are those who would be said to be of a "feminine" disposition. One influence which does much to favour the development of the disease is the want of a proper education. If the girl is fanciful and capricious, her parents yield to every whim. If she is morbidly self-conscious, she is allowed to indulge her vanity, and to nurse the belief that she is gifted and misunderstood. If she is studiously disposed, she is left to pore over books, and never gets proper exercise in the open air. If she craves for precocious excitement, she is taken to balls and theatres when still young, she is permitted to sit up late at night, to spend the morning hours in a soft bed, to live on a rich and stimulating diet, and to feed her imagination with romances. The influence of example may also induce a liability to hysteria; the daughter of a hysterical mother is very likely to acquire the disease in her turn; so potent does this cause appear to be, that according to the best authors there is no need to suppose that hysteria is ever transmitted by descent. In comparison with the emotional excitability in a girl, her intellectual capacity has but little influence either in rendering her susceptible of hysteria or in guarding her against it. As regards bodily constitution, some hysterical women are robust, with fresh-coloured cheeks and a vigorous circulation, but by far the larger number are weakly and delicate.

The real relations between hysteria and affections of the generative organs are best elucidated by the aid of the analogy afforded by some of the paroxysmal neuroses. We have seen that in many persons the attacks of megrim are constantly excited by disorders of the visual apparatus, but that in others this is not the case. We have found that vertigo is in some individuals brought on by diseases of the ear, and in some by diseases of the digestive organs, but that in others it is traceable to neither. So also it appears that the neurosis, hysteria, cannot essentially depend upon any one set of external exciting causes. In some cases it perhaps develops itself spontaneously. Very often anæmia or chlorosis appears to play the most important part in its causation, and it has sometimes been observed as the direct result of deprivation of food. In other instances—probably in the immense majority—its manifestations are directly called forth by impressions which reach the nervous centres from without. But these are by no means always derived from the generative organs. Emotional and psychical influences—a sudden alarm, the shock caused by the death of a relative, or the unexpected loss of property—may bring on hysteria in a person who had before seemed perfectly healthy. A similar result may follow a gunshot wound (as has been observed by Weir Mitchell), or it may be brought about by a railway collision. In some cases a spirit of imitation suffices for its production; the disease has been known to spread like an epidemic from one woman to another among the inmates of a hospital or a workshop. In other instances, as was pointed out by the late Dr Anstie, indulgence in alcohol seems to be the occasion of hysteria.

Again, it often happens that several of the conditions which may bring forth manifestations of hysteria are present together. A person who is

attacked after a sudden fright may before have had her health depressed by misery and exhaustion of mind and body, or may have been labouring under religious excitement, jealousy, wounded self-love, or remorse. The liability to hysterical symptoms of all kinds is always increased at the periods of menstruation, and there is reason to believe that it is also augmented in many women at the climacteric age, although this does not appear from statistical data.

But no doubt there are many cases in which disorder of the generative organs is really the main cause of the development of this neurosis, and it is practically wise to accept Addison's teaching that such disorder should be carefully searched for whenever it can possibly be supposed to exist. Fortunately we are able to investigate the state of the ovaries by pressure above the brim of the pelvis without offence to a patient's delicacy; but writers are by no means agreed as to the actual facts in regard to the frequency of ovarian irritation or other morbid conditions of the sexual apparatus in hysterical women. Jolly disputes the accuracy of Charcot's statements as to the proportion of cases in which hyperæsthesia of the ovary is present. He quotes Scanzoni and Amann as having found among their hysterical patients as many as 19 or 20 per cent. in whom the generative organs were perfectly healthy; and, as he remarks, the fact that these observers were professed gynæcologists renders it certain that their figures in regard to this point are too low. Speaking from his own impressions he is disposed to state the proportion of hysterical patients free from these complaints at more than 50 per cent. (Ziemssen's 'Handbuch,' xii, 2, p. 461).

Diagnosis.—That this is often difficult must be sufficiently apparent, not only from what has been said in the present chapter, but from the repeated references to hysteria which have occurred in our discussion of organic diseases of the nervous system.* In all doubtful cases it is important to search for the indications of hysteria which have been described above (p. 803). For example, anæsthesia limited to small portions of the cutaneous surface is probably present in many cases without the patient's knowledge, and its discovery may go far towards clearing up a doubtful case.

Hysteria mimics the symptoms of almost every disease of the nervous system, and also of phthisis and of abdominal complaints.

One must bear in mind that a woman may be hysterical and yet be affected with organic disease, either of the brain or of some other part of the body. This remark is true even of cases in which all the symptoms of hysteria are present in the most marked form, still more if we include its more aberrant or doubtful manifestations. Sydenham went so far as to say that the majority of women were hysterical; and since the psychical characteristics of this neurosis are after all only an exaggeration of those which belong to the whole female sex, it is obvious that no absolute boundary line can be drawn.

Again, it is important to note that there is no kind of proportion in the degree to which the different symptoms of hysteria are developed in the same patient. A woman who has hemianæsthesia, or paralysis, or some local pain may present scarcely any indications of emotional susceptibility, may be quite free from uncomfortable sensations in her throat, and may never have had the slightest approach to a hysterical attack. Yet the whole course of the case may show conclusively that the complaint is of this nature. Indeed, when one has to deal with the more marked affections, such as

* See Dr Buzzard's valuable remarks on the "Simulation of Hysteria by Organic Disease of the Nervous System," 'Brain,' 1890, p. 1.

paralysis or contraction of a limb, which is clearly not due to organic disease, one may be justified in making a diagnosis of hysteria, even in the absence of all corroborative evidence.

So, again, one may safely attribute to the same cause all cases of hemi-anæsthesia if unaccompanied by motor paralysis. And even when the loss of sensation is limited to a single limb, one would probably be seldom wrong in coming to the same conclusion. Sir William Gull, however, has recorded in full detail a case in which he at first made a mistake ('Guy's Hospital Reports,' Third Ser., vol. iv). A nurse in the hospital, aged thirty-eight, complained of numbness in the left arm. Below the elbow sensation was completely wanting; but when the skin of different parts above that joint was carefully tested with the point of a needle there were all kinds of contradictions in her statements. She would one minute say that she could feel the needle at a certain spot, and the next minute that she could not feel it. Such observations led to the conclusion that the case was one either of feigning or of hysteria; but after the anæsthesia had existed for two years the limb became gradually paralysed. Two years later she died from the effects of an accident, and it was then found that the spinal membranes were thickened, especially in the cervical region, and that the posterior columns of the cord and the grey matter had undergone degeneration.

In practice we must distinguish not only between hysteria and organic disease, but also between it and malingering; for the two are far from the same. An hysterical girl is proverbially deceitful, but when cured of her hysteria she is cured of her deceit. A malingerer deceives others, but not himself, and his self-control is unimpaired.

Prognosis.—The rule that hysterical fits are devoid of danger to the patient's life is not altogether without exceptions. Wunderlich met with a case in which a servant girl, aged nineteen, who had for eight weeks suffered from a succession of epileptiform fits of hysteria, unattended with fever, fell suddenly into a state of *collapse*, and died in two days with a temperature of 109·4°. Other cases have been recorded by Meyer in which excitement of a nympho-maniacal character was followed by cramps and spasms in various muscles, and led to collapse and death after an illness of some weeks.

Again, the more chronic forms of hysteria sometimes prove fatal by *marasmus* (cf. p. 821, *infra*). Dr Wilks has related in the 'Guy's Hospital Reports' for 1866 the case of a young lady who lost her sister rather suddenly by heart disease, whereupon she began to experience palpitation and sickness and pain over the heart, would take no food, declared that she had her sister's complaint and should soon follow her to the grave, and did actually die in a sort of hysterical convulsion exactly five weeks afterwards. He also gives the case of another girl who would eat nothing, but merely nibbled a biscuit and drank wine by drops. The bowels ceased to act, but masses of scybala were from time to time removed from the rectum. She became thin, and Dr Wilks at length renounced the opinion that the complaint was merely hysterical, and thought that there must be some partial obstruction in the small intestine. But when, at the end of more than two years, she died rather suddenly, he could find nothing to account for her illness. Her body was then fatter than when he first saw her, and she had in fact taken rather more food towards the last.

Treatment.—We must in the first place consider what degree of success may fairly be aimed at in dealing with hysteria. We can hardly expect to modify by drugs the peculiar morbid temper which underlies it, although

moral influences may strengthen the power of self-control. A complete cure of the hysterical tendency is seldom to be looked for, at least until the patient has passed the climacteric period. The earlier the stage at which the disease began to manifest itself the more unfavourable is said to be the prognosis. It is very important that a child who displays emotional excitability which seems likely to develop into hysteria should be placed under the most favourable hygienic influences possible. Exercise in the open air, a plain nourishing diet, limitation of the hours of study, early rising, sea bathing, and the use of the shower bath, at once suggest themselves as prophylactic measures.

When a hysterical patient is anæmic or chlorotic she should, of course, take one of the preparations of iron for a considerable time. If there be any uterine disorder it is generally advisable that the patient should employ some astringent injection for the vagina, such as the compound alum lotion which Addison recommended so highly, and which contains a drachm of sulphate of zinc and a drachm of alum in half a pint of water.

In dealing with special symptoms, again, one must never overlook the importance of moral treatment. This is often successfully employed in the management of hysterical paraplegia—an affection which is apt to persist for months, and even years, if left to itself. So, also, one can sometimes cure hysterical aphonia by urging the patient to speak and confidently assuring her that she is able. For this affection electricity, too, is very useful. Dr Reynolds recommends that sparks should be taken from the larynx; or that a shock should be administered from a Leyden jar; or that an interrupted current should be passed through the throat. In long-standing cases Sir Morell Mackenzie's instrument may be employed, by which galvanism is applied directly to the vocal cords. Each of these methods often leads to the instantaneous restoration of the voice. Dr Reynolds speaks of a strip of empl. lyttæ applied round the throat as having occasionally been successful when electricity had entirely failed.

Paralysis of the limbs may be treated with advantage by faradisation, and passive movements and frictions should also be diligently employed. But Dr Reynolds says that he has found no remedy so effectual as the application of a narrow piece of blistering plaster completely round the affected parts.

Hysterical anæsthesia is said to be sometimes benefited by the application of a rather powerful faradic current by means of a dry metallic brush. Stimulating liniments may also be rubbed into the affected parts.

The remarkable effect on hysterical anæsthesia of the application of gold coins, metallic bracelets, and magnets, and even of pieces of wood and other indifferent objects, attracted much attention a few years ago at the Salpêtrière Hospital (see the second Report by MM. Charcot, Luys, and Dumontpallier to the Société de Biologie, 'Brit. Med. Journ.,' 1878, vol. ii, p. 548). It is difficult, if not impossible, to unravel the underlying facts from the tangled mass of hysterical perversions, physical and moral; but any good effect which "metallothérapie" may have by its action on the imagination of the patient is more than exceeded by the attendant evils (cf. Dr A. H. Bennett's case, 'Brit. Med. Journ.,' 1878, ii, 563; and Dr Donkin's paper, *ibid.*, p. 613).

At present metalloscopy and metallotherapy have begun to recede whither the once famous "metallic tractors of Perkins" and the odic force of Reichenbach preceded them; and we hear more of "hypnotism,"

a revived mesmerism, and of "suggestion" in this induced hypnotic state.*

For rigid contraction of the limbs, the application of the continuous galvanic current is sometimes useful. But probably benefit more often results from straightening the affected joints under chloroform and placing the limb upon a splint, than from any other plan of treatment. Sir Thomas Watson speaks of cases in which a stream of cold water directed upon the contracted part and continued in spite of the patient's complaints of pain, led at once to the relaxation of the spasm. He also mentions an instance in which Sir Charles Clark cured by the same method a girl who had hysterical trismus and could neither speak nor eat. He began to pour pitchers of water upon her face, but before he had emptied the second pitcher she began to scream and complain, with her mouth open widely enough.

When hysteria manifests itself by producing a chronic and long-standing contraction of a limb, the administration of medicines seems to be altogether useless. But for most of the other effects of the disease drugs are certainly useful. Most writers speak of assafœtida and valerian as owing their virtues chiefly to their disgusting taste. But many hysterical women actually relish assafœtida. Moreover, pills containing valerianate of zinc ought on such a theory to be almost inert, whereas there is no doubt that, in doses of gr. j—ij, they are most effectual in removing aphonia, hemianæsthesia, and hysterical hemiplegia. In 1874 a woman was in the clinical ward of Guy's Hospital who had paralysis of her left arm and leg, the latter being rigidly extended; she took large doses of assafœtida for some days without benefit, but was afterwards quickly cured by the valerianate of zinc, so that she walked out of the hospital within five days from the time when she first began to take it. In other cases we have obtained equally good results with assafœtida, five grains of which were taken every three or four hours. Dr Reynolds has found bromide of potassium altogether ineffectual in any form of hysteria. Both he and Jolly recommend that opium or morphia should be given for the relief of pain and to procure sleep; and they rightly observe that for the former purpose the subcutaneous injection of the alkaloid is especially effective. But one must always keep before one's mind the evil results which may follow from the establishment of a morphia habit (see p. 429). The continued use of choral as a hypnotic is to be objected to on precisely similar grounds. And perhaps more harm is done by alcohol than by either of them. The late Dr Anstie was well justified in the strong protest he uttered against the practice of advising a hysterical woman to take a glass of wine or a teaspoonful of brandy, or even a dose of sal volatile to keep up her spirits whenever they are depressed, or to enable her to bear a frequently recurring pain. One should never sanction the employment of alcohol in any form by such patients, except perhaps in very moderate quantities and at meal-times only.

The system of treatment introduced by Dr Weir Mitchell is in bad cases sometimes useful. It consists in separating the patient from sympathising friends, making her eat, and using *massage* to the limbs.

When one is called to a patient who is actually in a hysterical attack, there are several methods by which one may succeed in cutting it short.

* See the late Mr James Baird's excellent little book, 'Magic, Witchcraft, Animal Magnetism, Hypnotism, and Electro-Biology' (1852); and Professor Heidenhain's 'Animal Magnetism,' translated by Dr Wooldridge, with a preface by Mr Romanes (1880). Mesmer was a Viennese physician who threw impressible patients into a *sommeil critique* by magnetised water. The same thing is now done in Paris by means of a revolving kaleidoscope.

One plan, suggested by Dr Hare, is to keep the patient from breathing for a certain time by forcibly closing her nose and mouth. The vigorous inspiration which she makes, as soon as she is allowed to do so, is said to be often followed by a relaxation of all spasm and a subsidence of the fit. Dr Reynolds says that he has found this mode of treatment notably useful when an attack is sufficiently prolonged to make it worth while to interfere with the natural course of events. Another method, to the value of which many can testify, consists in drawing the patient's head and shoulders over the edge of the bed and pouring cold water upon them from a large jug. Sometimes one has merely to make preparations for carrying out this procedure, by giving the necessary orders to the patient's friends in her hearing, in order to bring the fit to an end. An ancient hospital sister in Esther Ward never failed to cut short an outburst of hysteria among her patients by the same homely method.

Compression of one ovary will sometimes arrest a hysterical fit, even although it may be of an epileptiform kind; Charcot speaks of one patient who learnt to apply the pressure herself. Another procedure, often adopted by the late Mr Stocker, consists in pressing upon the arteries and other structures on each side of the neck, in the same way as has already been described under the treatment of epilepsy (p. 765).

One must always keep in remembrance the fact that, excepting in seizures of a strictly epileptiform character, the patient is perfectly alive to all that is going on, although she may seem to be unconscious. A calm and quiet demeanour, the avoidance of all expressions of sympathy or of uneasiness about the issue of the attack, may do much to shorten its duration; for if one is flurried or alarmed she is sure to notice it.

Catalepsy.—In some instances a hysterical attack is attended with very remarkable symptoms, which have long been regarded as belonging to a special neurosis named catalepsy (κατάληψις = a seizure or arrest). Its characteristic features are that the patient, although she may be deprived of sensibility and of voluntary motion, remains fixed in whatever position she occupied at the commencement of the fit, and yet that her muscles offer no such resistance to external force as would prevent the limbs from being easily bent or extended by another person, or the body from being placed in any posture. The condition of a cataleptic patient may be compared with that of a lay figure, such as artists use; if she is sitting up her arms can be put at the most awkward angles with the trunk, and will remain without falling, at least for a time; if she is recumbent her spine may be bent upon the pelvis so as to form an obtuse angle with the thighs, and will retain that posture. The name of *flexibilitas cerea* is sometimes given to this peculiar state of the muscles; they have been found by Rosenthal to have their electric sensibility and contractility either normal or decidedly increased. It is, however, a mistake to suppose that during the cataleptic state the muscles are capable of resisting the force of gravity for an indefinite length of time. On the contrary, the limbs, if extended, slowly fall again to the side. Dr T. K. Chambers quotes a case in which an impostor was detected by the simple plan of attaching a weight to the extended hands. She supported it without moving, and this was taken as showing that she was not labouring under a genuine attack of catalepsy; ultimately she confessed the fraud. The eyelids of a cataleptic patient may either be widely open or shut; in the latter case, if opened, they perhaps very slowly close again. The pupils

may contract under the influence of light. After recovery, all memory of what occurred is said to be lost.

These details of the "cataleptic" paroxysm appear to belong to this place, because it probably never occurs in a well-marked form except in persons who either are obviously hysterical or who at least may be strongly suspected. A case of the minor form of epilepsy was quoted (p. 750) in which it assumed a cataleptic character; but fully developed catalepsy does not appear ever to accompany epilepsy in a person of the male sex, or in a woman with no hysterical tendencies. The attacks seem almost always to be traceable, at least in the first instance, to a fright or to some other powerful emotion. Dr Chambers mentions the case of a girl, a patient in St Mary's Hospital at Paddington, who when Covent Garden Theatre was burnt down was awakened by the light flashing into the ward through the uncurtained windows; on the following morning she was attacked with catalepsy. The most striking instances of catalepsy which stand recorded are to be found in medical works of a time when the modern extended conception of hysteria was not dreamt of, and yet the reports of these cases often contain clear proofs that the patients were in the highest degree hysterical. The celebrated history related by Dr John Jebb nearly a century ago is a case in point. The subject of it was a young lady who suffered from hysterical risings in the throat and flatulence, and who was highly susceptible to every change in the weather. Although she was prepared for Dr Jebb's visit when he first went to see her, she was seized with the disorder as soon as his arrival was announced. "She was employed in netting, and was passing the needle through the mesh, in which position she immediately became rigid, exhibiting in a very pleasing form the figure of death-like sleep. . . . The positions of her fingers, hands, and arms were altered with difficulty, but they preserved every form of flexure they acquired, nor were the muscles of the neck exempted from this law, her head maintaining every situation in which the hand could place it, as firmly as her limbs. . . . About half an hour after, the rigidity and statue-like appearance being yet unaltered, she sang three plaintive songs in a tone of voice elegantly expressive, and with affecting modulation." The seizures sometimes lasted as long as five hours.

Trance.—In other cases similar attacks have been of still longer duration. The condition of the muscles has then been different from the *flexibilitas cerea* of catalepsy proper; either the limbs oppose considerable resistance to all attempts to change their posture, or they are completely flaccid, falling into any position whatever by their mere weight. Such patients may most fairly be said to be in a state of trance. Writers describe this condition as sometimes lasting for days and weeks at a time. The face may then be perfectly pale, the breathing so feeble as to be imperceptible except on the closest examination, and even the heart's pulsations and pulse at the wrist discoverable with great difficulty. These are the cases which have led to the popular belief that death is sometimes only apparent, and that there may be a danger of persons being buried alive; and it cannot be denied that a patient in such a condition might easily be allowed to die by careless or ignorant attendants, or might be buried before death.

Sleep-walking.—In other hysterical persons the attacks assume the form of somnambulism or of ecstasy. The former is a condition which may be compared to an acted dream. It is probably sometimes a transformation of epilepsy or some other paroxysmal neurosis; and when not allied to those

diseases it is almost always a manifestation of hysteria. The somnambulist, without seeming to wake from a state of sleep, walks all over the house and even out of doors. She balances herself without difficulty on narrow planks, and manages to avoid all obstacles in her path. She takes no notice of anyone whom she may meet, there is much difficulty in rousing her, she remains for a time bewildered, and she has no recollection of what she has been doing. Marvellous stories are told of the feats which are accomplished by persons in this strange condition. But one must not forget how untruthful hysterical patients often are, how prone to take a pleasure in mystifying and deceiving those about them, and how apt to be encouraged in such a course by the wonder which their performances call forth.

Ecstasy.—The state of ecstasy is one in which a person becomes regardless of all external circumstances and engrossed with some particular emotion or idea. She remains motionless, with staring eyes and fixed expression, or she may repeat a few words with ceaseless monotony. After she returns to consciousness she remembers the vision she beheld in the state of day-dreaming.

A similar state can be produced by mesmerism (or "hypnotism" or "electro-biology"), and is called by the practitioners at Nancy in 1890, *somnambulisme provoqué*. When this condition frequently recurs we have as a result what is called double consciousness, of which marvellous examples are from time to time published. A careful investigation of such cases might, amid much credulity and imposture, possibly discover some facts of physiological interest.

Chorea major.—Mental excitement naturally finds vent in muscular action, and rhythmical movements in turn increase and exalt emotion.

Religious dancing was common in antiquity, and survives as a minuet before the altar, which may still be seen in Seville Cathedral, and as the solemn gyrations of dancing dervishes at Constantinople.

In the Middle Ages there were epidemics of Dancing Mania, of which an interesting account will be found in 'Hecker's Epidemics of the Middle Ages' (p. 87 of Dr B. G. Babington's translation for the Sydenham Society). This Chorea major was also known as the Dance of St John the Baptist, as the Dance of St Vitus* (cf. p. 728), and in Italy as the Tarantula. It spread over Germany and the Netherlands in 1374, reappeared at Strasburg in 1418,† and was not extinct till the seventeenth century. Pearce, a traveller in Abyssinia, early in the present century, gives an account of a very similar dancing mania in that country, which was called "Tigretier," and Dr Davidson has described an epidemic among the natives in Madagascar which closely answers to the accounts of Chorea major in the Middle Ages. Similar cases in Scotland are described by Sir Walter Scott in his 'Demonology and Witchcraft,' and find a parallel in the religious dances of the "Jumpers" in the United States.

A remarkable instance of this kind was recorded by Mr Kinder Wood ('Med.-Chir. Trans.,' vol. vii). The patient, a young married woman, who had suffered severely with pain in one side of the face,

* Possibly the connection with this saint was through the dancing of the daughter of Herodias, but more probably it was because the old pagan festival of dancing and leaping through the fire took place on St John's Day at Midsummer. St Vitus was the patron and help in need of those afflicted with dancing mania, as St Martin in smallpox, and St Anthony in erysipelas.

† "Vier Hundert fingen zu Strassburg an Zu tanzen und springen, Frau und Mann,
Bis ihnen das Wüthen wieder gelag; Sanct Vit's Tanz ward genannt die Plag."

began to be troubled with involuntary movements in the eyelids, which were opened and shut with excessive rapidity. After a time the hands were beaten rapidly upon the thighs, and the feet upon the ground. Then she became half raised from her chair and seated down again, these movements succeeding one another as quickly as they possibly could. Other modifications of her attacks occurred from time to time, until at last she took to skipping about the room, regulating her movements by a series of strokes on the furniture as she passed, or by movements of her lips, as though beating a tune. Someone thinking he recognised the air as "The Protestant Boys" began to sing it, and she suddenly turned and danced up to him, and continued dancing until she was out of breath. Then a drum and fife were procured, and she immediately danced up as close to the former as possible, and went on till she lost the step, or until the measure was changed, or was made so rapid that she could not keep up with it. It was presently found that a continued roll of the drum put an end to her movements; and thus the attacks were at length prevented. The explanation which the patient gave was that there was always a tune dwelling on her mind which at times irresistibly compelled her to begin the involuntary motions.

Still more extraordinary movements were performed by a lady who came under Dr Abercrombie's observation, and who had suffered for two years from various nervous affections. While lying perfectly quiet, she would suddenly with her whole body make a kind of convulsive spring, by which she was jerked entirely out of bed. Or, if sitting or lying on the floor, she would fling herself into bed, or leap, as a fish might, on to a wardrobe fully five feet high. After a time the muscles of the back and neck became affected with a wonderful semi-rotatory movement, which sometimes went on without interruption night and day for weeks together. If the head or neck was touched, the motion was increased to extraordinary rapidity. She was cupped, and the affection suddenly ceased with a convulsive start of the whole body; but it returned again and again, and finally disappeared only when constipation and menstrual disorder were corrected.

Some years ago a similar case occurred in Guy's Hospital. A little girl, aged nine, had been knocked down by a boy five days before her admission. She was insensible at the time, and seven hours afterwards she had a fit. Subsequently she had nine other fits. They began by her making a low sighing or moaning sound, after which the upper extremity became contracted, the teeth were clenched, and with a sudden bound she threw herself completely out of bed. When she recovered consciousness she had no remembrance of what had occurred. On the day of her admission she had fourteen fits, and at one time she remained insensible for two hours. A day or two later she had two fits during the visit of the physician, Dr Owen Rees; in these she clapped her hands, and her face went through a most extraordinary series of contortions. In one attack she struck a part of her head to which a blister had been applied, whereupon she at once became conscious. After she had been in the wards six days one of the fits was commencing, when the nurse told her that she must be tied down: she immediately began to cry and recovered, saying that she would have no more fits. From that time she remained well.

For cases, in which vertical movements of the arm are incessantly repeated, the special name of *malleation* has been invented (cf. *supra*, p. 701).

Dr Wilks once had a girl under his care, who sat by her bedside and kept thumping with her fists all day long.

Gyration.—Hysterical movements of the head or the body round and round have been dignified with the special name of "*rotation.*" Several instances are related by Watson, of which the most striking, related by Dr Watt ('Med.-Chir. Trans.,' vol. v), occurred in Scotland in 1813. A girl, aged ten, who had before exhibited other nervous symptoms, was seized with a propensity to turn round on her feet like a top, with great velocity, and always in one direction. This continued a month, and then passed off. Afterwards she began to roll over and over on her bed, moving rapidly from one end to the other, for six or seven hours every day. Having been taken into a garden she quickly rolled along the whole length of a gravel walk, and even when she was laid in the shallow part of a river she began to turn round as usual, until she seemed on the point of being drowned. She made little or no use of her arms in performing the rotations. After another month she began an entirely new set of movements. Lying on her back she would, by drawing her head and her heels nearly together, bend herself like a bow, then she would relax her muscles, and fall with considerable force on her seat. This she repeated ten or twelve times a minute for several hours daily. After a fresh interval she began to stand on her head; and then to let herself fall again, her knees striking the bed first. This movement also she continued for fifteen hours a day, at the rate of twelve or fifteen times a minute. Blistering, purging, and leeching were employed without result; but having been taken to Glasgow from her home in the country in an open chaise, and brought back again after three days, she was seized with diarrhœa, and soon afterwards recovered entirely.

Maniacal excitement with hallucinations and delusions may complicate the hysterical attack. Such symptoms may be transitory, the patient becoming perfectly rational as soon as the fit passes off; but in many instances they last for a considerable time, and then it may be very difficult to distinguish the case from one of insanity. Many doubtful cases find their way into lunatic asylums, and the truth seems to be that no actual boundary line between hysteria and insanity exists. Dr Savage, in the twenty-first volume of the 'Guy's Hospital Reports' (1876), says that a large number of the female insane patients admitted into Bethlem Hospital have suffered from severe hysteria at former periods in their lives, and that many cases, at first regarded as examples of hysterical insanity, end in death or dementia. Some observers have made it a sort of test for hysteria that the mental faculties should be found unenfeebled when recovery takes place; and thus many doubtful cases have been at last set down as hysterical because of the suddenness and completeness with which the patients have regained their senses. Dr Savage speaks of one woman who imagined that she had the itch, and who refused to shake hands with anyone; she woke one morning quite free from delusion.

Hitherto we have not mentioned the occurrence, in a hysterical attack, of rhythmical *clonic spasms* at all resembling those which are seen in an ordinary epileptic fit; but spasms of this kind are not infrequently present, the other phenomena of the seizure being such as to leave no doubt as to its nature. In 1876 a girl was in Guy's Hospital whose main symptom was a rhythmical clonic spasm recurring at intervals of a few seconds in the neck, shoulders, and arms, and who had transitory fits in which she seemed to lose consciousness, while these jerking motions became much intensified

and succeeded one another with greatly increased frequency. One feature in that case was the perfectly bilateral character of the spasms, and this accords with the statements of writers to the effect that in hysteria the convulsive movements are rarely limited to one side, or much more severe on one side than on the other, whereas in epilepsy both conditions are frequent.

Epileptiform hysteria.—In some cases of hysteria, however, fits occur which in all respects resemble those of epilepsy. The loss of consciousness is complete; the eyes are widely open and the pupils dilated; a bloody foam escapes from between the lips, and the tongue is bitten; the movements are clonic rhythmical spasms of the simplest kind, and repeated again and again with but little variation. Perhaps this should not surprise us, for there are few diseases of the higher nervous centres (whether functional or organic) which may not be accompanied by similar attacks, of the most typically epileptiform character. But writers on hysteria, having probably in view the necessity of laying down a line of distinction between such fits and the ordinary hysterical seizures, have created for the cases in question the special designation of "hystero-epilepsy;" and there have been many discussions as to whether they are transitional links between the two neuroses, or instances of their co-existence in the same patient. But, as we have seen (p. 750), the disease epilepsy is defined not merely by peculiarities in the fits themselves, but by the fact that they recur again and again without any cause, unless it be an inherited tendency to nervous disorder. If it is theoretically inaccurate to regard as epileptic the fits to which some patients are liable for months or years as the result of the irritation of a carious tooth, it must be equally incorrect to give the name to the fits which occur only while a woman is under the influence of hysteria. And Charcot has recently pointed out that the so-called hystero-epilepsy differs altogether from true epilepsy in some important particulars. However closely the attacks may follow one another, they do not, as in the status epilepticus, entail danger to life with the development of a high bodily temperature. He relates the case of a woman who for more than two months laboured under a constant repetition of epileptiform fits. Once they succeeded one another without a break from 9 a.m. to 8 p.m.; and then again from 9 p.m. onwards for an equal space of time. He estimates that she had from 150 to 200 attacks on that one day alone. As he remarks, a patient suffering under epilepsy would soon have succumbed. The woman never passed urine nor fæces involuntarily, and got out to relieve herself in the brief intervals that occurred between the attacks. Her temperature rose occasionally for a short time to 101·3°; but the mean was 98·6°. As further distinctions between hystero-epilepsy and epilepsy Charcot alleges that the former never assumes the type of the *petit mal;* and lastly, that, however perfectly epileptiform a fit may be, it can always be arrested by compression of the ovary.*

Professor Mendel showed the Medical Society of Berlin in 1887 an apparently typical case of hystero-epilepsy or epileptiform hysteria, in the person of a man fifty years old.

* The extraordinary gestures of these unhappy patients have been carefully studied and named, as phases of "Ecstasie," of "Clownisme," and so on. See a report of a visit to Salpêtrière by Dr Gamgee ('Brit. Med. Journ.,' Oct. 12th, 1878); and details of cases in the same No., p. 561, with Professor Charcot's lecture, *ibid.*, p. 789. Some of the attitudes are shown to coincide remarkably with those of dæmoniacs in works of art.

Anorexia nervosa vel hysterica is a remarkable complaint which was described by Sir William Gull ('Clin. Soc. Trans.,' vol. vii). It is attended with extreme wasting, and is commonly supposed to be the result of some latent tubercular affection. But, remarks the writer, the emaciation is actually too great for this diagnosis to be correct; for persons with organic disease seldom become so thin as this until they are no longer able to get about, whereas it is characteristic of the hysterical anorexia that those affected with it display an excessive restlessness and bodily activity. In this complaint the pulse and the respiration are slow, and the temperature is generally below the normal. Sir William Gull's patients were chiefly young women between the ages of sixteen and twenty-three. It does not appear that any of them showed definite indications of hysteria. Some of his cases terminated fatally,* but in others a complete recovery took place, the main points in the successful management of them being the avoidance of fatigue, the administration of nourishing food at very frequent intervals, and the use of warm clothing.

It is in these cases that Dr Weir Mitchell's treatment by seclusion, with abundant feeding and regular shampooing or massage, is most successful.

Hysteria in male subjects.—As above stated, this remarkable neurosis or combination of neuroses is, in the vast majority of cases, a disorder of the emotions, the will, and the bodily functions of *women*—particularly incident to the periods of puberty, of early married life and of the menopause, but possible at any time after the infant has developed into the girl. Nevertheless undoubted cases of hysteria occur in the male sex, just as undoubted cases of hypochondriasis occur in women. It is extremely rare in full-grown men, but is not very uncommon in boys from the age of eight or ten to puberty and, less frequently, from that period till two or three and twenty.

In Dr Wilks's lectures on 'Nervous Diseases' there are several cases recorded. In one the principal symptom was so-called laryngismus, in another aphonia, in another convulsions which were supposed to be due to spinal meningitis, in another the "malleation" or hysterical hammering referred to above (p. 819). Sometimes the boy can be thrown into spasms like those of tetanus or of a frog poisoned with strychnia, as in a patient of Mr Holden's who was cured by removing a fatty tumour.

Dr Rühle, of Bonn, relates the case of a spoilt boy of fourteen, who had terrible convulsive attacks ending with vomiting, and was cured by "removal from home, cold shower-baths, and the fear of the rod" ('German Clinical Lectures,' p. 449).

The editor was once consulted about a schoolboy, who had twice been laid up at home on account of hæmorrhage from the bowels. He was ruddy and well nourished, and no disease of any organ could be discovered. A specimen of "melæna" was at last procured, and proved on examination to contain no blood, but a silver salt from a solution that he had used in photography. He then became violent and threatened to kill himself, but was soon cured by the wholesome discipline of a public school.

A naval surgeon gave a graphic relation in the 'Lancet' a few years ago, of a cabin boy of sixteen, who completely lost his voice and appeared to

* The writer once saw a fatal case of this form of hysteria. Extreme emaciation preceded death. At the autopsy there was confirmation of suspected vaginal irritation, but the organs were like those of starvation. The cord was normal to the eye, and histological examination revealed no lesion.

suffer from attacks of choking and suffocation. He was carefully treated for several days, until a sudden and unexpected pinch made him swear loudly, and thus revealed the imposture.

In 1888 we had in Philip Ward an apparently healthy young countryman, twenty years old, who, beside dyspepsia and hypochondriasis, suffered from "fits" of a decided neurotic character with well-marked globus hystericus.

HYPOCHONDRIASIS.*—From hysteria we pass to hypochondriasis by what seems a natural transition, for these two neuroses are commonly regarded as closely allied, and do in fact resemble each other in one prominent symptom—namely, their tendency to simulate organic diseases of various parts of the body. Indeed, some writers have gone so far as to declare that hypochondriasis, which chiefly occurs in men, is in the male sex the representative of hysteria in the female; and the uncertainty which still exists as to the relative frequency of hysteria in men and boys arises mainly from the fact that cases which would be at once set down as hysterical, if they occurred in women, are often wrongly attributed to hypochondriasis because the patients are of the other sex.

But hypochondriasis may be seen in women, especially about the time of the menopause, without any admixture of the proper characters of hysteria. Moreover, there is an essential difference between the two diseases. We have seen that the mental state in hysteria is characterised by an exaltation of the emotional faculties, and an increased susceptibility to outward impressions, the will being unable to control the feelings. But in hypochondriasis the morbid sensations which the patient experiences are not dependent upon any external cause; they are created by the mind itself. Thus Romberg was not without justification when he called it the antithesis of hysteria.

Again, hypochondriasis is unattended with any of those nervous vagaries —convulsive attacks, paralytic affections, hyperæsthesiæ, anæsthesiæ—which are so characteristic of hysteria. Its predominant symptom is always of one kind; the patient believes, without cause, that he is the subject of serious bodily disease. It is true that the full development of the complaint is often preceded by a period in which there is merely a general perversion of his feelings. He becomes gloomy, reserved, and wrapped up in himself; or his mental state alternates between a moody silence and high spirits with great loquacity. Presently, however, he becomes conscious of a pain in some particular region of his body, upon which he at once concentrates all his attention; and he is now a "hypochondriac."

The disease is one which has retained the same appellation since the days of Hippocrates and Galen. But they conceived the actual seat of the disease to lie in the viscera which are situated immediately below the diaphragm; and a similar hypothesis was intended to be conveyed by the equivalent English expression, "the spleen."† Indeed, it is the fact that the digestive organs are generally more or less disordered. Dyspepsia is often present; the bowels are constipated; large quantities of gas are apt to accumulate in the alimentary canal, giving rise to flatulent belchings and noisy rumblings in the abdomen. In all probability the starting-point of the morbid hypochondriacal feeling is really an impression

* Ὑποχονδριακὸν πάθος—Passio hypochondriaca—Passio atrabiliosa—Melancholia (in part)—Humor atrabiliosus—Milzsucht—The spleen.

† The first to vindicate the position of hypochondriasis among the neuroses was the celebrated anatomist Thomas Willis.

proceeding from the viscera, for among the symptoms of disease of the stomach and of the liver we shall find depression of spirits and irritability of temper. But what is peculiar to the complaint with which we are now concerned is the marked exaggeration of every local pain. Moreover, the region to which the pain is referred seldom, if ever, remains the same during the whole progress of the case. After having long dwelt upon a gnawing or burning pain at the epigastrium, which he felt sure must indicate cancer of the stomach or liver, the patient all at once loses this, and perhaps begins to suffer from symptoms which, if due to organic disease, would point to the throat as its seat. Or he is attacked with dyspnœa and palpitation of the heart, and feels convinced that he is labouring under serious cardiac disorder; or a slight cold leads to a cough, and he begins to collect the sputa, is certain that he is phthisical, and consults the physicians who have the greatest reputation for pulmonary affections; or he finds himself giddy, experiences a sensation of weight and pressure in the head, and forthwith thinks of nothing but of the apoplectic fit which he believes to be impending. But perhaps the most miserable of all hypochondriacs are those who refer their sufferings to the genital organs. To this class belong by far the larger number of those who consult one for spermatorrhœa, or for impotence. They complain that they have dragging pains in their testes, that these organs always hang too low, that their urine is turbid and must contain semen, that they have emissions at night, during defæcation, and at other times. One sees at once that their whole attention and thoughts are concentrated upon the sexual function; and to make matters worse, they are sure to have studied with avidity a number of books and pamphlets, written for the very purpose of stimulating their apprehensions, and of inducing them to seek relief from the quacks who write them.

If further evidence were required to prove that the disease is a neurosis, it would be afforded by the close relation which can be traced between it and other nervous affections. This was especially insisted on by Anstie, who maintained that the hypochondriac almost invariably belongs to a family of which other members have been of unsound mind. Unlike hysteria, hypochondriasis is markedly *hereditary*. As to whether the disease tends to pass into insanity in the same individual there is much difference of opinion. Melancholia is the form which bears the closest superficial resemblance to it; but Romberg points out that this is characterised by a tendency to self-negation, whereas in hypochondriasis the whole attention is concentrated upon personal feelings and sensations; and he goes on to show how the difference is expressed in all the patient's relations with other persons. A person affected with melancholia treats his medical attendant as an enemy or as an ignorant pretender, and constantly tries to avoid him; but the hypochondriac looks up to him as his guardian and saviour. He is constantly on the search for new plans of treatment, and expects that each fresh one will relieve him of his complaints. As Romberg puts it, "the more physicians, the better he is satisfied; he likes to change them as often as he would change a poultice." Yet, in spite of all, he is not unhopeful, and is never weary of life. A tendency to commit suicide is no part of hypochondriasis; and any doubtful case in which such an attempt is made may be safely set down as one of actual insanity. Probably the same may be said of every case in which the patient has distinct delusions, as (for example) that he is made of glass, or that the devil is playing a barrel organ in his belly, or that the bowels are about to escape through the abdominal

parietes, or that he has swallowed spiders, and that they are multiplying within his body. Griesinger, though so great an authority on mental disorders, seems to have entirely mistaken the boundary line between hypochondriasis and melancholia; the cases which he relates as examples of the former are almost all of them really instances of the latter disease (cf. p. 832). This perhaps explains the circumstance that he found hypochondriasis "extraordinarily frequent in young people," and occurring sometimes in the years of childhood. Gull and Anstie express the general opinion when they say that it is scarcely ever seen under the age of puberty, and very rarely makes its first appearance after fifty.

A point which must always be kept in mind is that a person labouring under well-marked hypochondriasis may also have organic disease—of the stomach, for example, or of the liver, or an aneurysm of the aorta. Many a patient has had his complaints made light of until the signs of one or other of these diseases have become too manifest to be overlooked, or until he has died suddenly, from rupture of a large vessel, or from angina pectoris. Anstie further remarked that in certain cases the possibility of malarial poisoning or of chronic alcoholism must be thought of before one sets down a patient's symptoms as the result of mere hypochondriasis.

The *treatment* of this disease is commonly difficult and unsatisfactory. An essential point is that one should not attempt to make light of the patient's sufferings, but should show oneself to be really interested and anxious to relieve them. Exercise, short of severe fatigue, should be taken daily, and mental occupation and amusement should be cultivated with the greatest care. Sea-bathing, the cold water cure, the warm baths of Gastein, may each be prescribed with advantage; but it is difficult to say how much of the benefit is due to change of air and scene, and alteration in the habits of life. Any disorder of the digestive organs must of course be carefully investigated and corrected. The continual exhibition of laxatives is injurious; it is better to depend on diet and exercise to procure a healthy state of the bowels. But an occasional blue pill and black draught are most valuable in many cases, and may be repeated once or even twice a week. Valerian is said to be sometimes useful, and so, with some patients, is tincture of sumbul. Neither quinine, strychnia, nor phosphorus is generally of service, nor iron, unless there be marked anæmia. Anstie rightly laid stress on the importance of not prescribing alcohol for hypochondriacal patients, even in the form of medicinal tinctures, lest by doing so one should encourage habits of over-indulgence in drink.

In weighing beforehand the probable success of treatment in a case of hypochondriasis, one has to take into consideration not so much the apparent severity of the symptoms as the length of time they have lasted and the circumstances under which they began. The younger the patient the better the prospect of cure; particularly if the family history is good, so far as regards the occurrence of insanity or other nervous diseases in his near relations.

PSYCHOSES

OR

DISORDERS AFFECTING THE MIND

(*By G. H. SAVAGE, M.D.*)

"Mentem sanari, corpus ut ægrum,

Insanity as a (1) *disorder of functions of brain;* (2) *an expression by the nervous system of bodily disease;* (3) *the expression of disease of the brain—Classification—Causation.*

Acute delirious mania—Acute and other forms of ordinary Mania—Melancholia with bodily complaints—Hypochondriasis, with mental complaints—true Melancholia—Stupor, active and passive—Delusional insanity—Hallucinations of the senses—States of mental weakness—by defect—by instability—Specially named varieties of insanity: puerperal, alcoholic, moral, syphilitic, gouty, plumbic, febrile, phthisical, asthmatic, cardiac, renal and diabetic—Epileptic insanity—Paralytic and tabid insanity.

Testamentary capacity—Certificates and other medico-legal points.

Idiocy and imbecility.

IN approaching the study of insanity, it is first of all important to remember that we have not a definite disease, such as typhoid fever or phthisis, to investigate, but that the condition or state called insanity depends, not only upon the evident symptoms, but upon their bearing on the social environment of the individual. There is, in fact, no absolute standard of sanity, and the divisions of the condition called insanity are to a great extent arbitrary. Insanity will have to be here considered chiefly from its clinical or medical aspect, but yet its social and its legal aspects must not be entirely neglected. Though there is no standard of sanity, yet it so happens that disorder of the nervous system expresses itself along more or less definite lines, and we shall have to point out the pretty regular association of symptoms as they occur in the different groups of insanity.

First we must recognise that while some cases of insanity depend upon cerebral disease or degeneration, others depend upon diseases of the body, which are referred to the nervous system; so that there is in the latter cases a mental aspect to a bodily disease. Thirdly, we shall have to consider the most difficult of all cases—those in which there is disorder of function without any visible pathological change in the nervous system. So, then, we have (1) disease of brain with disorder of its function; (2) disorder of some function or functions of the body with insane or nervous interpretations; and (3) disturbance or disorder among the functions or parts of mind.

While recognising *forms* of insanity, we must remember that these forms merge insensibly into one another, that no symptoms are absolutely characteristic of any one form of mental disorder. The *forms* are, then, arbitrary,

but more or less convenient, groupings of symptoms. The brain and nervous system have their special ways of expressing disease, just as the lungs, the stomach, or the kidneys have their special symptoms or ways of expressing theirs. We must look for the chief symptoms of insanity in either perversions of sensations, perversions of will, perversions of emotions, or loss of control or disarrangement of one or more of these parts of mind. The factors of mind for our present purpose will be considered to consist first of all, and perhaps most necessarily, of the inherited nervous system of the individual—the nervous basis; to which is added the experience gained by the various special senses—*perceptions*; and these bound together and arranged by *memory* form a structure upon which the *will*—balance of motives—and the *emotions* are supposed to play. And in each case of insanity it is well carefully to inquire first into the inheritance, next into the normal or abnormal working of the parts of mind as evidenced by the psychical and muscular expression. In considering the forms in which insanity appears, it will only here be necessary to make a few characteristic divisions, as the following:

Melancholic states, in which there are mental and bodily weakness and excessive self-consciousness.

Maniacal states, in which there is weakness with loss of control.

Dementia, in which there is weakness with more or less evident defect in mental function.

Beside the above, there are states due to the misleading by false sense impressions. These have been grouped under *Delusional insanity*.

The above are the more common groups into which symptoms of insanity form themselves. But these symptoms may occur in two distinctly opposite pathological states. They may occur as symptoms of disease of the brain, as seen in the degenerative process called "general paralysis of the insane," or they may occur in what we have seen to be the second and third groups of insanity. In fact, brain disorder, whether this occurs with brain disease, or bodily disease, or a disorder of mental function, expresses itself very much in the same way. Just as one may meet with cough which is due to disease of the lungs, cough which is due to a spasmodic condition, as in asthma, and cough due to defects in cardiac circulation, so we may have delusion due to organic disease of the brain, to bodily disease, as bad supply of blood, or to disorder of function, as seen in false sensory impressions.

Insanity occurs among the civilized and uncivilized, but in its more marked and serious forms it is specially a disease of the more highly civilized, and it will be seen that the more fatal forms of brain degeneration seem to increase directly in proportion to the high pressure of town life. Insanity is not, however, rapidly increasing in England. The statistics of the Commissioners in Lunacy show that whereas in 1875 there were 24·75 males, 28·43 females per 10,000 of the population in England and Wales insane, there were in 1885 respectively 26·61 males, 30·80 females per 10,000 in England and Wales insane, so that the increase is only about two per 10,000; and when we consider the greater general longevity and the consequent accumulation of chronic cases in asylums, it is pretty clear that there is no such increase of insanity in England and Wales as to cause real alarm. In further evidence of this the Commissioners' reports show that the admissions of fresh cases in 1886 were really fewer than the admissions of fresh cases ten years before. In fact, in 1875, while 5·36 men and

5·18 women per 10,000 inhabitants were admitted as insane patients, ten years later 4·8 and 4·9 respectively only were admitted.

In considering the so-called *causes* of insanity, the student must be warned that it is extremely rare to find one definite cause producing any attack of mental disorder, and it is therefore better to use the term *conditions* rather than *causes* of mental disorder. Again, though it is perfectly true that certain vital conditions, such as race, stage of civilization, climate, and the like, deserve to be considered as conditions predisposing to insanity, yet, in a short chapter such as the present, it is beyond our scope to consider more than a few of the general conditions which give rise to mental disorder. These causes may be divided for convenience into those acting chiefly upon the mind, and those acting chiefly through the body—the so-called *moral* and *physical* causes. These again can be divided into *predisposing* and *exciting;* and though some causes act distinctly as moral causes, yet it will be found that in the majority of cases one cause may be both moral and physical, and may also act as a predisposing and as an exciting cause. Take, for example, alcoholic stimulants, which act primarily as a physical and predisposing cause; but the associations of the drunkard are likely to lead him into moral troubles, which again react, and a fresh outbreak of drink and excitement may be the real exciting cause of the outbreak of insanity. The most common *moral* causes are mental anxiety, worry, overwork, money losses, religious excitement, love affairs, domestic trials, fright, and occasionally other emotions. Among the *physical* causes, intemperance, organic disease of the brain, injury to the head, venereal excesses, masturbation, epilepsy, pregnancy, parturition, and lactation are the more common causes assigned in England, and in addition to these, one of the most important conditions of insanity is *heredity.* It is extremely difficult to be sure of the part played by inheritance, yet it is sufficiently certain that a large proportion of people are insane because of the insanity of their parents. The insanity which is passed on from parent to child has special peculiarities, and will have to be referred to more in detail later on. There seems in such cases to be liability to disorder of function rather than to disease of the brain itself, and there also appears a greater predisposition to recurrence in cases with strong neurotic inheritance. Besides direct inheritance we have to remember that insanity may be developed in families where epilepsy, hysteria, hypochondriasis, some spasmodic nervous affections, and the like occur; and it is probable that if to these conditions in one parent be added any special cause of organic degeneration in the other, the offspring will be rendered more unstable, that is, more liable to fall out of step with the other members of a civilized society.

Causes of insanity act directly, *i. e.* immediately, only in very rare instances. The mischief is much more commonly the result of frequently recurring disturbance; and therefore in considering any case of insanity with reference to causation it is important that changes in temper, disposition, and habit should be carefully investigated. It must be understood that causes in the majority of cases are not easy to be traced, and in many cases the supposed *causes*, such as sleeplessness and dyspepsia and even alcoholism, may really be the earlier *symptoms* of the disease.

It is necessary to refer to a few of the general conditions in more detail. In cities degenerative changes and general paralysis are most common, whereas the latter is almost unknown in peasant races, such as the Celtic population in Ireland, Wales, or Scotland. Education is a cause of insanity if ill suited

to the nature of the person, but over-education alone is very rarely the cause. More women than men become insane, but more men have general paralysis and more women recover from insanity. Puerperal and climacteric conditions affect women. Insanity of any form may attack patients of any age, but in childhood the tendency is to idiocy, in early youth to imbecility, in youth to weak and impulsive mental states; in middle life the greatest amount of acute insanity occurs, as well as most general paralysis, at the climacteric melancholia and delusional insanity are frequent, and as age increases the tendency is to dementia.

Solitude and sedentary occupations followed apart are very dangerous conditions; hence widowhood is of evil influence. Domestic worry chiefly affects women, and business worry and anxiety men. Love affairs and sudden shocks, whether painful or pleasant, affect mostly women and very young people. All causes producing excessive nervous exhaustion affect the young most; as do also the abuse of stimulants and chronic poisoning, such as that by lead.

Injuries are not frequent causes of active insanity, but lead to diseases of degeneration. Tumours and coarse lesions of the brain, syphilis excepted, are also rare causes. Religious and political excitement act mostly as exciting causes. Fevers and any causes of delirium may start insanity.

Bodily diseases causing pain or weakness may set up nervous disorder. Insanity may depend on bodily disease, or on physical disfigurement and its moral effects. Insanity may alternate with other nervous diseases, such as epilepsy or hysteria, or it may alternate or replace other nervous or bodily diseases, such as asthma, gout, rheumatism, eczema.

ACUTE MANIA.—By acute mania we mean a state of mental weakness with marked loss of control. Under this head we shall have to place a variety of disorders extending from delirium to simple hysteria, and it will be convenient to make two distinct groups of the maniacal cases.

There is a well-recognised and well-understood condition—delirium; and formerly it was insisted that there were essential differences between mania and delirium, but it is certain that there are connecting links. There are cases in which there is some delirium but much maniacal excitement, and others in which there is little maniacal excitement and more delirium. It is well, then, to remember that when speaking of patients suffering from mania, we may have to consider either those in whom there is great bodily and mental disturbance or those in whom there is great mental disturbance with little or no bodily disease.

Acute delirious mania is a term used to express the symptoms occurring in the cases of mania in which the delirious element is most marked. Typhomania, brain fever, and other terms have been used, but it seems that we still are in want of some general descriptive term which will include all the cases which deserve to be grouped together, because, though most of these delirious cases are more or less maniacal, yet there are examples in which all the other bodily symptoms are present, but instead of mania there is either melancholia or partial weak-mindedness, or at least confusion of thought. Acute delirious mania is a disease most commonly met with in young people of both sexes. It is common in the highly nervous, the accomplished and educated. It is generally ushered in by a slow process of change in temper, or by general feelings of uneasiness, restlessness, malaise, or hypochondriacal symptoms. It is common to meet with young women

who have had some disappointment in love, some shock, or who have suffered from some physical disorder, producing nervous weakness or anxiety; they complain of sleeplessness and headache, loss of appetite, amenorrhœa, and general inability to apply themselves to ordinary occupations. This may be the early stage of acute delirious mania. Acute delirious mania may also follow shock, fevers, such as scarlet fever, measles, and the like; poisoning, as from belladonna, from intemperance in alcohol or ether, and in my experience it may also follow the inhalation of chloroform. It is not confined to young people. The period of depression may be followed quite suddenly by one of excitement, exhibited by voluble talking, exaltation of ideas, or not uncommonly by a rather sudden and startling development of erotic excitement. Within a few days the delirium has reached its height: the patient then has the appearance of one suffering from typhoid fever, lying on her back with a tongue dry and brown, or thickly coated, with sordes on the lips, the eyes suffused, the cheeks either sallow or (during periods of excitement) brightly flushed, the lips moving without any audible result, the hands twitching or picking the bedclothes, the voice, if heard, harsh and raucous, the skin moist, with but slight increase of temperature; then rapid emaciation, tendency to bedsores, and excitement recurring irregularly, but most marked at night, with little or no reaction to the surroundings. There may be hallucinations of sight and hearing. There may be periods of tranquillity and apparent recovery followed by periods of excitement. During the period of excitement there seems to be no memory. Patients recovering have little or no recollection of what has happened during their illness. It is almost impossible to say how long the period of excitement will last, but from a few weeks to two or three months is the limit, and it must be remembered that patients suffering from acute delirious mania are passing through a process in which exhaustion is the chief characteristic, and the excitement is invariably followed by a more or less prolonged period of depression, the depression not being that of melancholia, but rather that of inability to will or to desire, so that they are in a will-less, childish condition. From one third to one fourth of the young cases suffering from acute delirious mania die, and of the others probably a full third remain permanently weak-minded. Some rapidly gain flesh, but remain dull, apathetic, and unlike their former selves. Others pass into general paralysis.

The chief points in *treatment* are to feed freely and abundantly. It is well to begin with a free purge by means of calomel or croton oil, and then to follow up with beef-tea, mutton broth, milk, brandy, and eggs. It is almost certain that artificial feeding will be required. Feeding by means of a nasal tube—or better, by putting a funnel in one nostril, and, while controlling the other, slowly pouring the fluid food down the nostril—will be found of great service in these cases. The feeding by a stomach-pump, by the rectum, or by the nose, must be repeated every three or four hours, and it is of the utmost importance that stimulants should be given without stint. In old days it was feared that with such apparent excitement of the brain stimulants would have an injurious effect, but all modern experience is that stimulants, instead of causing excitement to these patients, are more likely to produce rest. In many cases the excitement is so extreme that some form of restraint, medical or mechanical, must be used. Chloral hydrate, in doses of from fifteen to thirty grains at night, and repeated in ten-grain doses two or three times a day if necessary,

may be tried, but it is better to do without any narcotic if possible. In strong, young, active people the wet pack, *i. e.* the rolling the naked patient in a sheet wrung out of tepid water, and then rolling one or two blankets outside this sheet, and placing the mummified patient on the bed for from one to three hours, will produce rest and quiet, but this treatment should be carefully watched by a skilled nurse, and during the process food and stimulant should be given. In some cases, in the earlier stages, warm baths with mustard in them will produce a stimulating effect upon the skin and secure a good night's rest. The great point to remember is that patients suffering from acute delirious mania are suffering from a disease which, as a rule, either rapidly kills or rapidly passes off, leaving the patient much exhausted, and as soon as the acute attack has passed it is of the utmost importance that they should have careful nursing, without much change in their surroundings. After the illness rest and quiet in the country or by the seaside is preferable, in the writer's opinion, to travel; and it should be remembered that in such cases intellectual work should not be undertaken for a twelvemonth from the onset of the disease.

Complete or only partial recovery may take place; the patient may be left more or less morally or intellectually crippled, and in some cases not only is there defect of mind, but, following the acute delirium, some more or less permanent wasting with contraction of the lower extremities may occur, and the writer has met with cases of delirious mania in which general paralysis has followed and made rapid progress.

There is no very marked tendency to the recurrence of attacks of delirious mania. In fact, delirious mania differs in that as it does in other respects from many forms of ordinary acute mania.

ORDINARY ACUTE MANIA.—In this condition, unlike the last, we have more organised expression of delusion, and more marked loss of self-control with less bodily disturbance. The conditions under which maniacal excitement appears are endless, depending much upon the inheritance, education, race, and other peculiarities of the individual. We meet with every variety, from simple uncontrolled lust to violent homicidal destructiveness, and no one description can fully cover the whole line. Mania may occur as only part of a morbid mental process; it may follow a melancholic stage, or epilepsy; it may be part of *folie circulaire*, or recurrent attacks of insanity; it may be part of the symptoms in general paralysis of the insane or of dementia due to age or definite brain disease. But in all cases the symptoms are sufficiently alike to deserve one description.

The *causes of mania* are in no way special. Mania may follow from moral or physical causes, may follow injury to the brain, direct or indirect, or may follow upon bodily disease or disorder. A shock may produce either mania, melancholia, or dementia.

Nearly all cases of mania begin with uneasy feelings about the epigastrium, occasionally with feelings either of emptiness or fulness of the head, rarely with headache or photophobia. Sleeplessness and fear of impending ruin are common, anorexia, constipation, restlessness, inability to apply themselves to work, irritability, and emotional weakness. This period may last from a few weeks to several months, and may become extremely marked and profound. After the period of depression the patient may almost suddenly grow more restless, more excited, and markedly loquacious. He may say that he has been ill, but that now he is quite well,

and he may become extravagant, boisterous, and over-generous. He may discover that he does not require to sleep so much or to eat so much as he did, and he may be full of ideas that he will be able to make a fortune by some invention. Any interference by his friends is resented, and in many cases such early interference precipitates the attack of mental excitement. Sleeplessness of a restless type is marked, appetite is variable, a craving for stimulants may occur. The bowels as a rule are confined, the skin is often sallow, but of normal temperature, hallucinations of sight and hearing are not uncommon in the earlier stage, delusions as to property, wealth, position, and also as to the actions of friends, are common. Will as a rule is unstable, so that the patient is incapable of persistent effort. He is often emotional and irritable, but his memory is so far good that he remembers what is said or done, though things appear to him different from what they would in health. Sexual desire is frequently great, but there is probably no increase of sexual power. The general bodily condition is one of weakness, and the general mental condition is one of instability and mobility.

The two things that one has to guard against chiefly are the reduction of strength and the infliction of injury to self or others; the real question of treatment depends almost entirely upon the question of danger to the patient or his friends. Mania may end fatally from sheer exhaustion; this occurs mostly in elderly patients, or in people exhausted from some general bodily disease. A large number of maniacal cases get well, but a certain number remain either permanently weak-minded or permanently unstable, so that they are constantly liable to recurring attacks of insanity. Of those who do not sink in the earlier stage the period of excitement may last for weeks or months; probably four or five months is an average period for acute maniacal excitement to persist. During this period there will almost certainly be intervals during which the patient is more quiet and apparently improving, and it is noteworthy that after a night's sleep, produced either by narcotics or as a result of exhaustion, the patient may appear to be improving; but we must be prepared for remissions and relapses in the course of ordinary acute mania. During the maniacal excitement destruction of clothes and filthiness of habits are very common and distressing. Each individual case exhibits peculiarities in its course, symptoms, and termination. Patients often suffer from some bodily ailment before the mental storm begins to pass; one will complain of headache, another of neuralgia, one of rheumatism, and another of restless sleepless misery connected with some trifling bodily ailment before the disappearance of the excitement. As a rule the symptoms disappear slowly, it being noticed that the patient is getting more self-control, has greater desire to see friends or relations, writes letters home, is anxious to see to his business, and very probably may be discontented with his situation. Discontent in persons suffering from mania is equivalent to the returning consciousness of a man who has been stunned; and just as in the latter case there is for the patient himself a painful consciousness, while for the onlooker there is the satisfaction of sensibility returning, so also discontent in the maniacal patient often means returning consciousness. In proportion as the patient has been excited will there be depression or mental exhaustion; and it is pretty certain that a prolonged attack of mania will be followed by a prolonged attack of mental exhaustion or depression, during which there may be more or less sleeplessness and loss of appetite, with general mental weakness; but in these cases

change of surroundings and as speedily as possible a return home will be found the best treatment.

From a practical point of view, all powerful narcotics and depressants are merely means to keep a patient within control, and not means of really curing our insane patients. It will be necessary in some cases to try chloral, bromide of potassium and the like, and it undoubtedly in a few cases will be found that bromide of potassium alone or combined with chloral will lessen the excitement and give time for the patient to recover. But the most important consideration is that, whatever treatment is followed, we must be sure not to affect the appetite or we shall have cause to regret it. Abundant nourishment, with or without stimulants, associated with exercise in the fresh air and as much freedom as is possible, should be the treatment for such cases. Sulphonal is useful and appears to be harmless.

Before leaving the consideration of this group, we must mention the patients who have suffered from acute mania and who never permanently recover. Some, as already stated, remain ever after liable to recurrence of insanity, others remain weakened in some special way so that they are unable to fulfil their duties as before. Thus, one individual will be morally weak and is called either a kleptomaniac or a drunkard, another becomes emotionally weak and takes to ambitious schemes for reforming his fellows or to spending day and night in religious exercises, a third becomes volitionally weak and allows himself to be looked after and attended to by his friends without any desire to help himself.

It is only necessary to add that, if the antecedent stage of melancholy be long, the maniacal one is likely to be prolonged also.

After epilepsy very violent mania is frequent, and chloral given by the mouth or the rectum may check the mania if administered early after the fit. Cases in which the mania depends on senile changes are less favourable but not hopeless.

Maniacal excitement due to general paralysis generally passes off in a few weeks. Mania due to alcohol is very variable, but may last for weeks or months.

MELANCHOLIA.—By the term *melancholia* we mean a state of unreasonable mental depression; grief without a real cause, depending rather upon a physical than a moral determinant.

Melancholia may be but part of the disordered process or may be the whole of the morbid state. In most cases of acute mania and in most cases of general paralysis of the insane there is a stage of melancholia which ushers in the acute symptoms. Melancholy as a form of mental disorder occurs in all ages, though probably it is most commonly met with in and after middle age. It is most common in the dark complexioned. The symptoms of melancholia may depend on general depression of the vital powers, or it may depend upon some special diseased process, as, for instance, heart disease. The most characteristic symptom at the onset is extreme self-consciousness. This develops into grief which is variously expressed; irritability of temper, sleeplessness, loss of appetite and suicidal tendencies develop in order. Melancholia has been divided into many varieties. The chief methods of division depend upon the outward expression of the morbid grief. In some the symptoms are *active* and in others they are *passive*,—in the former the patient restlessly wringing his hands and openly complaining, while in the latter he is struck dumb by his misery. Melancholia is divided

not only by its expression but by its special aspects: in one the expression of grief is in relationship to the bodily functions, while in the other the mental symptoms predominate. The former may be called *hypochondriacal melancholia*, and the latter *true melancholia*. Every shade of melancholia may be seen in relationship to hypochondriasis, but in an asylum we see the more exaggerated cases which must be secluded in consequence of their desire for death and refusal to take food.

Hypochondriacal melancholy.—There are four distinct groups of cases which come under this head. First, there are those patients whose one complaint is that they are dying and that nothing can be done for them, though they make no definite complaint of any special organ.

Next we have a large group of cases in which the symptoms are referred to the *head*. Thus young patients will tell you that their brains are hot or wasting or hollowed or melted, and women about the climacteric will complain of opening and shutting of their brains, of something coming away when they move their necks, or the like. Older patients will complain of adhesions between the brain and the skull, or of miraculous removal of brain and nerve power.

The third group includes those who believe that some terrible calamity has befallen their *digestive tract*. One patient believes that his throat is stopped: these symptoms are allied to exaggerated hysterical globus. Another is sure that his stomach is ruptured or imperforate, or that some connection exists between the stomach and the circulatory system. A few patients imagine that the rectum is permanently closed. All these cases have to be looked upon as exaggerations of hypochondriasis, cases in which every hypochondriacal symptom is greatly developed.

The last group of insane hypochondriacs contains those who believe that some trouble arises from their *reproductive organs*. Middle-aged men believe that they have been rendered impotent, that their testes have withered, or that by some evil habit or by some course of medicine they have become emasculated. Such cases are more commonly met with among men than among women. It is comparatively rare in asylums to find women with uterine and ovarian hypochondriasis. There are young sexual hypochondriacs whose disorder is partly due to masturbation, and these have varying disorders of the brain.

In all cases of hypochondriasis the one object of *treatment* must be the withdrawal of the attention as much as possible from the sensitive part by occupation, while the general health is being improved. Judicious change of air, change of scene, travelling and mechanical occupation, with withdrawal from old associations and companions, are of the utmost value. Such cases recover in a fair proportion, but if past middle age, or if the development of morbid ideas has been slow, and if there be no definite physical illness associated with the mental disorder, the prognosis is bad. Such patients rarely become weak-minded, but persistently hold to their hypochondriacal delusions, which may remain for many years, the rest of the intellectual life of the patient being normal.

Ordinary melancholy.—Ordinary melancholia consists in emotional depression, in which the explanation of the feelings is moral and not physical. It may be the result of shock, or grief, or bodily illness. In certain predisposed persons any cause which reduces the vital standard below a

certain point seems to be able to produce melancholia. The first symptoms are, as a rule, mere uneasiness, restlessness with inability to take interest in surroundings, tendency to tears and emotional disturbance, dread of some impending calamity, with undue sensitiveness to the conduct and the remarks of others. These symptoms are associated with loss of appetite, sleeplessness, and feeble circulation, as seen in winter by chilblains and cold extremities, together with loss of appetite, constipation, and amenorrhœa in women. These evidences of reduced power are all part of the process, and may rapidly pass into most pronounced mental depression. Up to this time there has been a feeling of misery, but there has probably been little or no explanation as to its cause. Later hallucinations of the senses or delusions may arise, and these depend to a great extent upon the education, age, and immediate surroundings of the individuals, so that the young woman thinks that her virtue is called into question, while the old man thinks that he is going to the workhouse. It is common to hear patients in this condition refer to their past wickedness, and to say their souls are lost, that they are possessed by the devil, that they are "the Scarlet Woman," that they are metamorphosed into beasts, or are unnatural, and that they ought to be dead. At this time they will be sleepless, and probably will refuse to take food voluntarily. There will be complete inaction of the bowels and general apathy and listlessness; suicidal tendencies become marked, and it is important to remember that patients as a rule select a special form of suicide which they prefer, and will wait for an opportunity rather than seek death by any other means. Suicidal attempts are mostly to be feared when patients believe themselves to be impotent, when they believe themselves to be injuring their nearest relations, or when they dread being tortured "to make them confess," or when they believe themselves to be followed and dogged about. Patients who "hear voices" are also very liable to suicide. The melancholic process is, as a rule, longer than the maniacal one, and an average of from six to eight months is required for recovery. The symptoms, after slowly advancing, may slowly recede, the prognosis depending really upon the steadiness of the improvement both in mind and body. In some the cure is sudden after sleep or after some sudden improvement in general health, as improved digestion or the like. Perfect recovery may take place, or, what is more common, there may be a slight excess of excitement after the melancholia has passed away. There is a great tendency to relapse in melancholic patients, especially in those belonging to an insane stock. A certain number of patients die from melancholia, but as a rule the cause of death is secondary to the mental disease, there being some congestion of the lung or extreme exhaustion and emaciation depending upon bad nutrition or insufficient feeding. In cases of chronic melancholia wasting of the brain is well marked, and the pia mater is sodden and easily separable.

The *treatment* of melancholia naturally divides itself into preventing harm and doing good. The first essential is to prevent suicide, and this is only to be done by constant watching, by the utmost care in the selection of nurses, and by insisting on the patient having his rooms on the ground-floor. Rest in bed, especially during the colder months, is valuable, warmth and food, with stimulants, being very important. In some cases of active melancholia morphia may be useful. When patients are treated at home, it is necessary to give narcotics, the rule being not to give them continuously, to avoid giving them in increasing doses, and to vary them as much as possible.

The next most important thing is the method of feeding. Patients

who refuse their food absolutely may be fed by the rectum, by the mouth, or by the nose. As a rule, patients who resist should not be fed by enemata. In feeding by the mouth, if sufficient care and time be taken in nearly all cases food may be given in small quantities by the spoon being introduced by the side of the teeth. But if resistance be great it is better to pass a nose-tube or the stomach-pump. The nose-tube is very easily passed, and nurses can be trained in a few lessons to do it without danger; a large-sized soft catheter fixed on the end of a small glass funnel is all that is required, the tube being passed down one nostril, while the other nostril is compressed by the finger. Three to five pints of milk, six eggs, two pints of beef-tea or broth, and four ounces of brandy, may be given in twenty-four hours.

Among the forms of melancholia the most important are *simple melancholia*, that is, melancholy without delusions; *melancholy with stupor*, to which we shall refer again; and *active* or *resistive melancholia*, in which an active expression of grief occurs. There is no special form of melancholia deserving the terms "religious" or "suicidal."

Simple melancholia is often present in men of middle age and of active intellectual habits. Misery without cause, self-accusation about trifles, sleeplessness and loss of appetite, inability to apply the mind or the attention, are the chief symptoms.

A month's rest under supervision, away from wife and friends, followed by restful and recreative travel, are all that is needed; but probably twelve months' rest from mental labour will be beneficial. This state may occur in much-examined youth, in much-worked or worried manhood, or may appear at the climacteric or decline of life. Suicide is common. There are other varieties of melancholia associated with bodily disease. Thus, undeveloped or suppressed gout may be represented by melancholia, and phthisis may show itself only as progressive weakness and refusal to take food, with suicidal impulses. Melancholia, if of an active type, often benefits if morphia be given, and in young cases shower-baths are of service. In gouty and simple cases a course of Turkish baths will often work wonders.

STUPOR, INCLUDING ACUTE PRIMARY DEMENTIA AND MELANCHOLIA WITH STUPOR.—Under this one head two very distinct groups of cases are included, but in both of these the characteristic symptoms are the stupor, the silence, and the abstracted appearance of the patients. According to some there is no such thing as acute primary dementia without delusions, all these patients owing their mental attitude to some dread or terror. In fact they believe such patients to be in a kind of chronic panic, but it will in any case be necessary to distinguish between two groups occurring under this head, and for convenience we will call them the active and passive groups.

Active Stupor.

Common in adolescents, who have a terrified expression, are wasted and thin, with skin purple and cold, resist or are cataleptic, refuse food, are sleepless, wet, and dirty, have distinct delusions of dread, retain memory through the attack, refuse all food and require abundant forced feeding with stimulants; electricity and massage may be useful.

Passive Stupor.

The passive form occurs more frequently as the result of some cause of exhaustion in young or middle-aged people, who have a silly aspect, muscles are flabby, skin greasy, limbs relaxed; they eat what is given them, sleep well, are clean if watched; there is no evidence of the existence of delusions, little or no memory on recovery; and for treatment they require baths, exercise, and general tonics.

The above groups resemble one another in history and in progress to a great extent; most of them occur in young adolescents. It seems as if in certain weak-minded persons there is energy enough for boyhood or girlhood, but when manhood and womanhood comes on it fails. With such cases shock, grief, masturbation, disappointment, overwork, unhealthy occupations, fevers, intemperance, rapid childbearing, or the like, may suffice to produce the breakdown. When once the condition of stupor has been established, as a rule it persists for several months, though occasionally there are recurrences of stupor between intervals of sanity. Little or no good comes to these cases unless the general health can be markedly improved. The patient, if in active stupor, is probably more or less cataleptic, and has to be forcibly fed. He wastes, and is wet and dirty, is very liable to secondary inflammations, and often has chilblains. He takes no notice of his friends. The stage of stupor is of very variable duration and may end in death, in slow or sudden recovery, or in partial weakness of mind.

This state of mere passive stupor may be uniform and persistent, but commonly it is associated with periods of temporary recovery or of periods of excitement, or with sudden outbreaks of impulsive violence. This passive state frequently results from or follows an acute stage of mania, or develops after some severe and exhausting bodily illness.

Feeding, warmth, and watching are of great service. One danger in such cases is death from some secondary complication; local inflammation or phthisis may develop and terminate rapidly. After recovery there is frequently a period of exaltation during which sexual desire and tendencies to lust and intemperance may arise. The prognosis depends greatly upon the family history. If neuroses are common in the family, and if the patient is very young or badly developed, or if he have a badly shaped head, or any tendency to phthisis, the prognosis becomes absolutely bad. If a patient recover from stupor it is very necessary that for some years he should be carefully watched, and he should not return to any occupation which involves severe strain either of mind or body, so that it is much better after recovery from stupor to send the patient for one or more sea voyages, or, if possible, to let him follow some mechanical or outdoor life.

DELUSIONAL INSANITY.—So far we have considered states in which there have been perversions of the whole mental functions associated with more or less bodily disturbance, but under this head we have to consider cases in which the perversion of the senses is the chief symptom. The expression "out of one's senses" is recognised as meaning madness, but only some patients are definitely out of their senses. Such are the cases now to be described. It can readily be understood that as our intellect depends to a great extent upon the impressions we receive and store up from our senses, if our senses mislead us the intellectual result will differ greatly from that of the ordinary standard. The cases which I have to describe depend chiefly upon hallucinations, which are sense impressions not depending upon any external or objective impressions. Thus a person who in the stillness of the night hears "*voices*" has hallucinations of hearing, and the person who, similarly situated, has *visions* or smells *poisons* or tastes *filth* is suffering from hallucinations of the senses of sight, smell, and taste respectively. Hallucinations of hearing are the most common, next in order we have hallucinations of sight, then in order those of touch, taste, and smell. Nearly all hallucinations may be reckoned as painful nervous impressions. The explanation which is given

of the sensation depends to a great extent upon the education and occupation of the individual.

Patients suffering from *delusional insanity* are generally past middle life, single or widowed, often of insane family, leading solitary lives or fulfilling positions which are uncongenial to them in one way or another. Hallucinations have been frequently traced to solitary confinement in prison, and I have met with several cases in which they have developed in men living isolated lives in the wilder parts of India and other English dependencies. As a rule the earliest symptom complained of is nervousness and nervous weakness. Patients become excessively sensitive, and this leads to a condition in which everything seems to point to or to affect the individual; his mind is like the tender corn to the walker, and just as every movement seems to affect the latter, so every action of others seems to be directed against the former. He becomes suspicious, jealous, bad-tempered, more and more solitary, and this increasing solitude further develops the ideas of *suspicion*. He believes himself to be *persecuted* and *followed about*. He may think that his thoughts are read by others or appear aloud to himself and to others so that they read his secrets, he hears people coughing, jeering, or making allusions to him or to his family. He may hear words such as "devil," or worse, constantly whispered in his ears; he may then take the law into his own hands and assault some one whom he believes to be his persecutor. The ideas of interference may become more organised, so that he is convinced that bodies of men, such as the Jesuits or the Freemasons, are interested in his ruin. Under these circumstances the patient becomes exceedingly dangerous, and, unfortunately, it is very hard to break through the hallucinations and to appeal to him by means of any other ordinary sense impressions which might in time loosen the bands of the false sense impressions. If these symptoms have developed slowly for twelve months the prospect of recovery is very slight. Patients who believe themselves to be followed or persecuted should be most carefully secluded or watched with the utmost care as they are both homicidal and suicidal. They are sometimes so exceedingly suspicious that they will deny their delusions so as to mislead those of whom they are afraid. Besides those who believe themselves to be persecuted there are others who believe that everything refers to them, and others who believe that the whole of their sense impressions are make-believes,—that the whole world is a kind of play which is being acted before them.

The general *treatment* of cases suffering from delusional insanity must depend very greatly upon the nature of the delusions, and the length of time which they have existed. Medical treatment is practically useless, but in some cases persuasion, associated with change of surroundings, works wonders. One young man believed that his relatives jeered at him from the roof, and that others made use of foul terms against him and them. This patient was excessively violent, yet by employing him, amusing him, and bringing distinct irrefutable evidence that these people did not exist on the roof and did not accuse his friends of iniquity, we slowly brought him to be more amenable to discipline, and at the end of twelve months he was discharged so far recovered that he has since emigrated and is now in perfect health.

CHRONIC WEAK-MINDEDNESS.—Loss of faculties, more or less general, may result in such extreme mental weakness that it is unsafe for the patient to be at large, as he would on the one hand be a tool for the wicked

and on the other a prey to the vicious. Chronic weak-mindedness, as seen in an asylum, may result from age, apoplexy, course of brain disease, or it may follow nervous exhaustion, general paralysis, brain tumour, epilepsy, or any other conditions of nervous or mental excitement.

Simple *weak-mindedness* is *gauged* by *loss of memory* and *loss of control*, and every variety may be seen, from the weak-minded imbecile to the lustful and dangerous, demented lunatic. The general course of ordinary weak-mindedness due to age and the like is as follows:—Progressive loss of control of the emotions, loss of memory and tendency to collect articles of no value on the one hand, while there is thoughtless and reckless extravagance on the other, a redevelopment of lust and a tendency to intemperance, which all lead to a wastful expenditure of the reduced nervous capital. Often patients who have led reputable lives up to sixty may pass through every phase of moral degradation before it is discovered that their immorality was the result of arterial degeneration. Such cases require to be recognised and to be rather watched than sent to asylums, if the means are sufficient, because the probable termination of such cases is an apoplectic fit or permanent childishness.

Among the subjects of chronic weak-mindedness we must include a large number of patients who, having suffered from acute attacks of mania or melancholia or stupor, instead of recovering their old mental balance, remain either *permanently crippled* or *permanently unstable*. The permanently crippled may exhibit their weakness by loss of one or more of the higher faculties, so that one becomes impulsive and homicidal, another ceases to respect truth and honesty and is called a kleptomaniac, another disregards decency and becomes altogether brutalized. In some a single faculty, such as memory, may seem to be affected out of all proportion to the others; the most characteristic loss after all is that of the highest social relationships. Patients who have not perfectly recovered from acute attacks of insanity invariably lose their affection for near relations and friends, and pass into a condition of philosophical calm or social indifference. Besides the loss of faculty already described, there are cases of permanent instability. Every asylum contains patients who are subject to recurrent attacks of mania or melancholia, patients who during twenty, thirty, or forty years periodically have recurrent attacks resembling in every particular the previous ones, with the probable exception that each attack is rather longer than the former, and leaves some more or less well-marked scar upon the intellect. Among these we have to recognise cases of chronic recurrent mania and of chronic recurrent melancholia.

Another group remains, and that is of those cases which, after an acute attack of insanity, have a few symptoms surviving, organised as it were, so that the patient becomes automatic, with certain peculiar actions or modes of thought fixed. Thus one patient for sixteen years sobbed out hour by hour, "I don't know what to do," and yet there was no sorrow in the later years, the lamentations having become purely automatic, and the patient eating well, sleeping well, and becoming fat. In other cases with chronic chattering incoherence, there may be persistence of some hallucinations, so that the patient is living in two mental worlds, or perhaps it were better to say between them; hearing faintly the real messages from the one, and more clearly the false impressions from the other. Many such cases, though violent at first, may be treated with sufficient safety at home, as is evidenced by the existence in so many country places of feeble-minded

villagers, ready to run an errand or enter into boyish games. Such weak-minded persons may be trained to perform mechanical tasks sufficiently well, so that the simple drudges of an asylum are often patients suffering from chronic feebleness of intellect.

So much for the permanently crippled. The permanently unstable are those who though fairly reasonable during most of their lives are constantly subject to fresh attacks. In some, the recurrences are at long intervals, and are comparatively harmless to the nervous system; in others the frequency or severity of the attacks causes progressive destruction of mind.

The symptoms may be maniacal or melancholic. Each attack as a rule resembles its predecessors in mode of development, symptoms, and mode of termination, but each attack may further impair the stability.

A patient may have an attack of acute mania and recover, a second attack occurs in four years, a third in three, a fourth in two years, and after that one or more attacks may occur yearly till the patient either passes into chronic mania or into hopeless weak-mindedness. In cases of recurrence, if maniacal symptoms are present, powerful drugs such as hyoscyamine in one tenth of a grain, given subcutaneously, may check the outbreak or the recurring habit, especially if the drug be given when the earliest sign of disturbance is noticed.

In recurrent cases of melancholia with suicidal ideas, with each recurrence suicide must be guarded against. Therefore such cases are always anxious ones if allowed to be at large.

With the unstable cases hereditary tendency is common. Such cases may live to an ordinary age. In some cases a weak-minded state gives place periodically to outbursts of violence.

PUERPERAL INSANITY.—There is no special form of insanity deserving the name "puerperal" yet, as the puerperal conditions are not infrequently causes of insanity, the term Puerperal Insanity is convenient.

Insanity may be developed during pregnancy; it may be but an exaggeration of the longings of pregnancy, and on several occasions a distinct connection has been traced between some absurd or morbid appetite and a neurotic tendency.

Beside the mere longings of pregnancy and their insane exaggeration, one meets with true insanity occurring early in pregnancy. This is most common in women who have already suffered from some form of insanity before. Thus, a woman who has had one or more attacks of puerperal insanity is liable to a development of this disorder with a succeeding pregnancy. Insanity of pregnancy may occur in the earlier months, and may pass off spontaneously about the fourth month, or the insanity may develop during the later months of pregnancy, and in that case will probably not pass off till long after delivery. As a rule, the insanity of pregnancy is of a depressed type, the patient being suspicious, jealous, refusing food, dreading poison, and irritable. Sleeplessness, refusal to take food, and tendency to suicide or infanticide, are the most dangerous symptoms and those which have to be the most guarded against. The induction of premature labour is generally useless; and the best treatment is to improve the general health by change of scene, removal from home, or at least removal of children from home, withdrawal of husband's society, and careful watching.

The second group of cases of insanity with pregnancy contains those that

have become insane after the fourth month. Such cases have frequently suffered much from exhaustion, due to frequent childbearing, repeated lactations, and vomiting of pregnancy. They may be maniacal, but usually suffer from melancholia, with ideas of unworthiness, and are strongly suicidal and often infanticidal; some suffer more from simple nervous exhaustion and stupor. The treatment of these cases resembles that usual for such conditions—rest and food, and removal from home.

It is rare for the insanity to pass off permanently with delivery. In some cases during the pains of labour, and immediately after, there is a temporary improvement, but as a rule the sanity following labour in these cases is temporary.

The next class to be considered contains those who become insane soon after delivery. Puerperal insanity occurs in a very large proportion among women with distinct insane inheritance. The causes are of long standing, rather than sudden; repeated pregnancy, poverty, exhaustion from sickness during the pregnancy, or several of the above causes combined, and though there are few noteworthy symptoms till after delivery, yet we should be prepared to find, on careful investigation, that there have been threatenings and warnings which have been neglected.

Within two or three days of delivery occasionally there is a temporary or transitory maniacal attack allied to the febrile disturbance associated with the oncoming of milk, and, like that, the transient mania may be relieved by a free purge. It is noteworthy that in this transitory mania infanticide or suicide may occur.

Insanity occurring after labour is divided into that which befalls the puerperal woman at once, and that which develops within the first two months after delivery. The former contains the greater number of maniacal cases, and the latter the more melancholic. Puerperal insanity does not follow instrumental labours in any great excess. Quite natural and easy labours are frequently followed by puerperal insanity in predisposed subjects. Puerperal insanity has undoubtedly a great tendency to recur in the same individual, but may not recur unless she become again pregnant. Puerperal insanity may be characterised by either maniacal or melancholic symptoms, or from the first there may be stupor. The onset of the disorder is generally as follows:—Sleeplessness for several nights, with irritability, loss of appetite, and querulousness, especially against the husband and child; then increased irritability or anxiety, with ideas of poisoning and refusal to take food; afterwards appear hallucinations of the senses, violent outbreaks occur, or profound melancholy may develop, in the one case the woman being destructive, and in the other suicidal. During this period the milk and lochia may be natural; on the other hand, one or both may be absent. From a practical point of view it is necessary to attend carefully to the milk, and to follow the old wives' simpler methods of "dispersing the milk" rather than making use of belladonna and other poisonous drugs. Friction with castor-oil or the application of hot salt are useful.

An attack of puerperal insanity usually lasts for several months, and requires most careful watching and care. The patients rapidly emaciate, often neglect themselves, and develop some secondary disorder which often proves fatal. There is no more special danger in the insanity than there is in the puerperal condition, but the two combined require double care in their treatment. Abundant feeding is the rule, with removal from home, and the sparing use of chloral or bromide of potassium.

The period of excitement may be unduly prolonged, so that in some cases patients are maniacal for eight or ten months before there is any sign of abatement of the disorder. Among the most characteristic signs of puerperal insanity in its later stages is the patient's discontent and jealousy of her husband, her tendency to mistake those who are about her, and the appearance of a weak-minded stage which is extremely difficult to treat. Following an acute attack of puerperal insanity we must expect to have a prolonged period of depression; and as soon as the patient has ceased to be actively antagonistic to her husband and home, and especially as soon as she expresses a desire to return to her family, it is desirable to make some movements in that direction. It will be found at this period that the patient gets stout, indolent, sleepy, and sometimes is too contented with an asylum; amenorrhœa also exists, and frequently this amenorrhœa and general condition of apathy are only relieved by return to home and domestic cares.

In such prolonged cases a second pregnancy is particularly hazardous; and in all cases of puerperal insanity it is of the utmost importance to impress upon the husband the danger of another pregnancy occurring within at all events two years.

Seventy-five per cent. of puerperal cases recover, about 5 per cent. die, and 20 per cent. remain chronic. Of those who recover, the majority recover slowly; mental and bodily health improve together. Of those who die, some die from septicæmia, but more from exhaustion due to the weak bodily condition associated with the mental excitement. Of those who are uncured, a large proportion have had many previous attacks, but a certain number of patients do not recover from their first attacks of puerperal insanity, and it is therefore well to be guarded in the prognosis even from the first.

Beside puerperal insanity, we have a form of mental disorder associated with *lactation*. From two to three months after delivery patients become suspicious, sleepless, irritable, and inclined to wander from their homes. In some cases there is amenorrhœa, but more often menorrhagia, due probably to incomplete involution of the uterus. These patients are sallow and anæmic, with bad appetite and constipated bowels; they frequently suffer from hallucinations of smell, taste, and hearing.

As a rule they require merely tonic treatment. They recover in the course of two to six months if removed to healthy surroundings, and away from home cares and worries. They require warmth, food, stimulants, fresh air, and, in the summer, baths, and the seaside.

ALCOHOLIC INSANITY.—Although no one special form of insanity depends upon drink, yet there seems to be some relationship between alcoholic intemperance and the variety of insanity. It is therefore well to recognise the chief forms assumed by insanity depending upon drink.

Sudden outbursts of drink in nervous subjects will lead to delirium tremens, and delirium tremens, instead of passing off as it ordinarily does, assumes in such cases more or less the character of a chronic delirium. With some patients acute delirious mania follows an acute alcoholic debauch. In such cases the removal of stimulants will not suffice to cure directly, and the persistent use of opium is rather injurious than otherwise. Hallucinations of sight and hearing similar in all respects to those met with in delirium tremens occur, but are more persistent; refusal to take food is constant,

emaciation takes place rapidly, and, unless the patients are fed abundantly with milk and nutrient soups, a fatal issue may be expected. If the patient be young and strong, a purge by croton oil and an emetic of sulphate of zinc may be found the best treatment to start with. If the excitement seems likely to wear out the patient, chloral alone or with bromide of potassium may be given at night, but it is best not to give these drugs continuously or in too large doses.

Beside the acute mental disturbance produced by alcohol, we meet with every variety of delusional insanity, patients believing that their food is poisoned, that they are being watched, spied upon, and the like. Jealousy with vindictiveness is very often met with. Insane interpretations of morbid cutaneous and muscular feelings also occur; thus patients will complain of being galvanized, mesmerized, or "interfered with." The prognosis in those suffering from delusional insanity due to alcohol is not very hopeful, and in any case they should be kept under observation for many months before they are discharged as *well*. In some cases the morbid sensations persist and the morbid interpretations remain, and yet they cease to be active agents upon the patients' will, so that we meet with chronic cases of alcoholism, with chronic delusions, who are able to be at large without danger to themselves or friends. Chronic alcoholism probably tends in some cases to the production of general paralysis of the insane; it is much more certain that it tends to senile dementia, and in the cases of senile dementia connected with alcohol there is a great tendency to apoplexy, hemiplegia, and paralytic weakness of mind.

It is legal to send a patient suffering from alcoholism into an asylum if he cannot be controlled, or if he be dangerous to himself or others; yet we ought to be extremely cautious in signing certificates for persons suffering from chronic alcoholism with symptoms of insanity, for though seclusion will restore them to their former mental state, that is not a healthy or normal one, and the prospect of legal proceedings is in such cases considerable.

MORAL INSANITY.—It may seem unphilosophical to describe a form of insanity as belonging to the moral apart from the intellectual side of man, but the term will perhaps appear clearer to some readers if moral insanity be defined as a perversion of the nervous system by which the man or woman is rendered "anti-social." To give an idea of what is meant I would say there are two distinct conditions under which moral insanity may exist: first, the children of insane or highly neurotic parents seem in many cases to come into the world unable to grow up into full intellectual and moral capacity; secondly, there are certain diseases of the brain or disorders of the mental functions which, having upset the nervous balance, leave a fresh moral standard far below what was the normal and healthy standard of the individual. Thus there are some patients who are unable to develop into their moral and social places, and there are others who having filled their proper positions are, as the result of disease reduced to a lower moral rank.

First as to the young patients, the offspring of parents who have been drunken, epileptic, or insane, not uncommonly are morally rather than intellectually insane. They are perverse and incapable of being trained into their duties to society. Thus they are frequently precocious and sexually vicious, they are cruel, mischievous, untruthful, thievish, and at times pyromaniacs. At the same time these persons may have one or two special gifts.

Thus, they may be extremely rapid calculators, they may be able to reproduce musical combinations, or they may have wonderful memories for isolated facts. As a rule such patients require isolation. As they grow older they become more dangerous from their sexual passions and from their destructive tendencies. They often pass into eccentric, weak-minded drudges in asylums.

Beside these we have to consider those who are morally weak as the result of acute attacks of insanity. After acute mania some young patients will be left kleptomaniacs, others will have lost their self-control and become amorous and impulsive, others cease to be truthful and in one way or other show marked anti-social qualities. In these cases again there is little or no prospect of recovery,—they are like people who have been scarred by the smallpox, and nothing will ever efface the marks.

Not only after mania but after other forms of mental disorder, moral defects may become manifest; and similar changes may follow fevers. Temporary, and in a few cases permanent, moral changes have been observed to follow an attack of typhoid or rheumatic fever.

Moral perversion may occur as an early symptom of general paralysis of the insane; it is common with alcoholism and is frequently seen in the earlier stages of senile dementia. In some cases the faults or vices of old men are really the result of early degeneration of the brain.

Moral insanity is scarcely capable of medical treatment. In the case of many young and middle-aged persons the best and indeed the only course is to let the delinquent receive the due punishment of his faults. The discipline of the jail has undoubtedly done good in some cases. Such young persons will ruin themselves and their friends, and if steps are taken to send them to asylums, they often retaliate and cause endless legal trouble.

Syphilis may give rise to various forms of insanity. The moral effect of the consciousness of transgression may set up hypochondriasis with syphilophobia, and this may end in general paralysis of the insane. Syphilis may produce local brain lesions with various degrees of mental weakness; or epilepsy, which may likewise lead to the same result. Syphilis may give rise to arterial changes which may lead to dementia, or to paralysis ending in dementia. In a considerable number of cases of general paralysis of the insane there is a history of syphilis.

It is not uncommon to find patients who have suffered from syphilis and who have recovered from some secondary symptoms such as ptosis, external strabismus, or hemiplegia, pass into weak-mindedness or into conditions hard to be distinguished from general paralysis. In a certain number of weak-minded children and idiots, and in some elder patients, congenital syphilis has produced sensory or intellectual weakness. In any case of insanity in which syphilis has previously occurred, anti-syphilitic drugs should be used; but in most cases resembling general paralysis or with marked mental defect no good result will follow such treatment.

Gout may occur in neurotic families and may be of special importance. Before and after gouty attacks there are often marked mental changes in patients, and in some cases of so-called suppressed gout most profound and suicidal melancholia may occur only to pass off when active gout appears. Gout may seem to alternate with insanity as with asthma or eczema. Gouty degeneration of arteries is not uncommonly associated with signs of senile decay and dementia.

Lead-poisoning may produce maniacal excitement or it may end in dementia. The same poison may produce all the symptoms met with in general paralysis, and may almost certainly give origin to that disease. It also leads to epilepsy and its results.

After *fevers* it is not uncommon to meet with more or less mental weakness, which does not depend much upon the severity of the fever. This is not uncommon after typhoid fever, and may range from simple loss of memory to loss of control and mania, with emotional disturbance. In persons of highly nervous temperament, the delirium of any fever may set up mental disorder, which may appear as acute delirious mania or, more commonly, simple acute mania.

Phthisis is related to insanity in many ways. The insane are more than usually liable to phthisis. Insanity in one parent and phthisis in the other gives rise to a very unstable type of mind. Many patients who recover from severe attacks of mania or melancholia die a year or two afterwards of phthisis.

A form of insanity called phthisical insanity has been described. The patients are suspicious, and refuse their food because they believe it to be poisoned; they often have hallucinations of taste and smell, and of hearing; they rapidly waste, without having any cough or expectoration; the temperature is more or less like that of phthisis, and dulness is found if sought for under the clavicles. These patients require forcible feeding with stimulants and cod-liver oil. Hæmoptysis with temporary relief to the mental symptoms is not uncommon.

Spasmodic asthma often occurs in neurotic families, and it may occur in persons who have had attacks of insanity. In some cases the spasmodic attacks disappear and the patient becomes melancholic, only being restored to his right mind when the asthma returns.

Heart disease may act as a cause of insanity; mitral incompetence being most frequently associated with feelings of distress, anxiety and melancholia, while aortic lesions, and at times mitral contraction, have been met with associated with mania and great excitement.

With *renal disease*, the tendency is toward mental depression.

Diabetes is not uncommon in neurotic families nor is it very rare in insane persons; but generally with the onset of insanity the diabetes disappears.

Epilepsy and insanity are allied by origin. Epilepsy occurs in neurotic subjects, and epilepsy in infants causes idiocy or imbecility. Frequent recurrence of epileptic fits, whether in the major or the minor form, leads to weak-mindedness. Hallucinations of the senses may precede the fits; and after them periods of unconsciousness may follow, during which highly complex acts may be performed, the patient being in a state allied to somnambulism (cf. *supra*, p. 820). Epileptic fits may be followed by fury of the most violent kind, during which brutal and bloody deeds may be done (p. 754).

Convulsions may probably be replaced by mental disorder—"l'épilepsie larvée." In this the patient after a sudden arrest of the work in hand goes through more or less highly organised acts unconsciously; these acts in each recurrence are usually alike, and just as each epileptic fit is a repetition of its predecessors, so is each mental attack like its forerunners.

Jacksonian epilepsy is not so frequently followed by mental disorder as is the idiopathic epilepsy which occurs in neurotic subjects.

Paralytic insanity.—After apoplexy there is a great tendency to weak-mindedness. This is not always enough to deprive the patient completely of self-control, but it often leads to loss of memory and to a certain want of self-control manifested in erotic lust, in emotional weakness, and in a tendency to be easily influenced by others. It commonly passes from the slighter to the graver forms of dementia, especially if fits recur.

Tumours of the brain generally tend more or less certainly to loss of some of the functions of the mind.

In *locomotor ataxy* we frequently meet with a neurotic history, and in many cases ataxy is an early symptom of general paralysis. But besides, with locomotor ataxy there may be outbreaks of mania, generally of a suspicious, jealous nature; or the symptoms of the disease may be falsely interpreted by the patient: he may say that his legs are electrified and his sexual power removed by his enemies, or he may accuse people of twisting his bowels or destroying his sight.

If the symptoms are part of general paralysis, the prognosis is bad; but if due to locomotor ataxy, the prognosis is much better as far as length of life is concerned.

ADMINISTRATIVE CAPACITY.—One of the most important duties of the medical man is to be able to judge of the mental capacity of a patient who may have had some attack of insanity or other nervous disturbance. First, it must be remembered that some persons who have been insane recover completely, and may be able to transact business as well as ever; that the prospect of recovery and of mental capacity is lessened with the increasing number of attacks and with increasing years. Wills may be made by persons who are chronic lunatics, and yet the wills may be so reasonable that judge and jury will support them. It is important to remember that to upset testamentary capacity it must be shown that the patient had *no* knowledge of what he was doing, or that he had mistaken ideas about what he was effecting, or that his judgment was biassed by delusions of one kind or other, or that, being weak, he was unduly influenced. Defective memory is a thing to be specially noted. If it can be shown that a man when making a will did not remember the number of his children or whether they were living or dead, there would be ground for disputing that will. If, on the other hand, it can be shown that he was emotional and easily led by others, even though the memory was not very defective, yet it might be shown that he was too readily influenced at the time he made his will by those who were near him. If it can be shown that he had a causeless antipathy —the result of a delusion—to his direct heirs, it is only necessary to prove the nature of those delusions and their existence about the time the will was made. Apoplexy probably gives rise to weak-mindedness more frequently than any other disease of the brain, and the mental weakness produced by apoplexy certainly gives rise to the greatest number of trials in the probate courts. A man may have one or more attacks of apoplexy and yet may remain of "disposing" mind; but it is well to remember that after fits of apoplexy memory is very frequently affected, emotional disturbance is readily raised, and other signs of weakness and change of character are generally present.

There may be complete testamentary capacity without capacity for

speech, in fact aphasia and weak-mindedness are not necessarily related; but it may be found difficult to get a jury to understand that a person unable to give the name to the simplest object may yet be able to dispose of his property. This difficulty will be greatly increased if agraphia also is present.

THE CONFINEMENT AND RESTRAINT OF INSANE PATIENTS.—One of the most difficult points for a medical man to decide is as to whether a patient should or should not be sent to an asylum; and having decided on sending a patient away from home, the next difficulty arises as to where the patient should be placed.

For the reception of persons of insane mind there are houses receiving one patient only; this is called *single care*. These houses are without any license, and no certificate is necessary for many patients so placed. But it must be understood that, even though a patient be placed in "single care," it will be necessary to have the ordinary medical and other certificates in due and proper form, if he is so insane as to need his actions to be controlled.

Beside houses which receive only one patient there are others, *licensed houses*, for the reception of two or more, and these merge insensibly into the private *asylums* which are to be found in most counties of England. Next there are registered *hospitals* into which patients are received at various rates, the principle of the hospital being that while some patients are received free or for small sums, others pay more than their actual cost, and thus help to pay for the treatment of the poorer ones. There are also the large borough and county *asylums*, expressly intended for the reception of those who are not sufficiently wealthy to pay for private asylums, and who, from one cause or another, are ineligible for hospitals. Lastly, a certain number of quiet harmless lunatics are confined in the *workhouses* and workhouse infirmaries.

If a person of unsound mind is to be removed to the borough or county asylum, it is necessary that notice should be given to the relieving officer of the parish, who in due course reports to the medical officer of the same parish or some other medical man; and the patient being brought before a magistrate, and the medical man having certified that he is of unsound mind and unfit to be at large, the magistrate signs an order for the transference of the patient to the county asylum. If a person of unsound mind be found wandering about the streets, he may be given in charge of the police, and, being taken before the magistrate, a doctor being called by the magistrate, may give evidence which satisfies the justice of the peace that the person is of unsound mind and requires detention; and then he may, on the magistrate's order and the medical man's certificate, be sent to the asylum. There are special provisions for cases in which no magistrate is available, or when the magistrates decline to act; thus two medical men signing a certificate can practically enforce the removal of a patient to a county asylum. No patient can be kept or retained in a medical man's house for profit except under full legal certificates, unless he be a near relative, it being manifest that no one's liberty of action must be restrained to the advantage of another without legal authority.

There must now be *two medical certificates* on separate sheets of paper (one of these being by the regular medical attendant), a *statement* of particulars in the form given, and a *petition* to a magistrate or judge specially named for the duty, which must be accompanied by the other papers, viz. the medical certificates and the statement; the magistrate then satisfies

himself of the correctness of forms and the necessity for the detention of the patient, and signs *the order* for his reception into any hospital or private asylum or private house. A patient may be sent to any asylum on one medical certificate and the statement, provided that at once steps are taken to get the petition and other certificates after his admission (see *Urgency Form*). Patients may place themselves in asylums voluntarily with the consent of the Commissioners.

FORMS 1 AND 2.

Form of Urgency Order for the Reception of a Private Patient.

I, the undersigned, being a Person Twenty-one years of age, hereby authorise you to receive as a Patient into your (a) _____

(b) _____

as a (c) _____ whom I last saw at _____

on the (d) _____ day of _____ 189 .

I am not related to or connected with the Person signing the Certificate which accompanies this Order in any of the ways mentioned in the Margin (e). Subjoined [*or* annexed] hereto is a Statement of Particulars relating to the said _____ .

(Signed)

Name and Christian Name at length _____

Rank, Profession, or Occupation (if any) . . . . . _____

Full Postal Address . . . . _____

How related to or connected with the Patient . . . . _____

Dated this _____ day of _____ 189 .

To (f) _____

_____

[In cases of urgency a lunatic person may be placed under care and treatment upon an Urgency Order made (if possible) by the husband or wife, or by a relative (*i.e.* a lineal ancestor or lineal descendant, or a lineal descendant of an ancestor not more remote than great-grandfather or great-grandmother), accompanied by a Statement of Particulars and one Medical Certificate. If a Petition for an Order for Reception of the patient has been already presented to a Judge, Magistrate, or Justice, a copy of the Urgency Order must be sent forthwith to such Judge, Magistrate, or Justice. An Urgency Order will remain in force for seven days from its date, or if a Petition for a Reception Order is pending, then until such Petition is finally disposed of.

The Urgency Order, Statement of Particulars, and Medical Certificate must be sent to the Superintendent or Proprietor of the Asylum, Hospital, or House where the patient is to be received.]

(a) House *or* hospital, *or* asylum, *or* as a single patient.

(b) Name of patient.

(c) Lunatic, *or* an idiot, *or* a person of unsound mind.

(d) Some day within two days before the date of the order.

(e) Husband, wife, father, father-in-law, mother, mother-in-law, son, son-in-law, daughter, daughter-in-law, brother, brother-in-law, sister, sister-in-law, partner, *or* assistant.

[*If not the husband or wife, or a relative of the patient, the person signing to state as briefly as possible*:—1. Why the order is not signed by the husband *or* wife, *or* a relative of the patient. 2. His *or* her connection with the patient, and the circumstances under which he *or* she signs.]

(f) Proprietor *or* superintendent of —— house, *or* hospital, *or* asylum (describing house *or* hospital *or* asylum by situation and name).

LUNACY 4 and 2.

(52 and 53 Vict. c. 41.)

This, accompanied by the *Statement*, will suffice to remove a person of unsound mind to an asylum, when the further certificates can be obtained.

STATEMENT OF PARTICULARS.

Statement of particulars referred to in the annexed petition.

The following is a statement of particulars relating to the said

(*Name of Patient in full*) _____

N.B.—*If any Particulars are not known the Fact is to be so stated.*

Name of Patient, with Christian Name at length . . .	_____
Sex and Age	_____
Married, Single, or Widowed .	_____
Rank, Profession, or previous occupation (if any) . .	_____
Religious Persuasion . .	_____
Residence at or immediately previous to date hereof . .	_____
Whether First Attack . .	_____
Age on First Attack . .	_____
Give the dates. WHEN and WHERE previously under care and treatment as a lunatic, idiot, or person of unsound mind . . .	_____
Duration of existing Attack .	_____
Supposed cause	_____
Whether subject to Epilepsy .	_____
Whether Suicidal	_____
Whether dangerous to others, and in what way . . .	_____
Whether any near Relative has been afflicted with insanity	_____
Names, Christian Names, and full Postal Addresses of one or more Relatives of the Patient .	_____
Name of the Person to whom notice of Death to be sent, and full Postal Address if not already given . . .	_____
Name and full Postal Address of the usual Medical Attendant of the Patient . . .	_____

How many previous attacks? _____

Has the Patient been of Sober Habits? _____

Number of Children? _____

Age of youngest? _____

Degree of Education? _____

Signed, _____

When the Petitioner or Person signing an urgency order, is not the Person who signs the statement, add the following particulars concerning the Person who signs the statement.

Name, with Christian Name at length .	_____
Rank, Profession, or occupation (if any)	_____
How related to or otherwise connected with the Patient	_____

N.B.—*The Patient must be received into the Hospital before the expiration of Seven clear days from the date of the Judge, Magistrate, or Justice's Order.*

ORDER.

Order for reception of Patient, to be made by the Judge of County Courts, Stipendiary Magistrate, or Justice appointed under the Lunacy Act, 1890.

I, the undersigned (*Name*)_____
being the Judge of the County Court of _____
or the Stipendiary Magistrate for_____
or a Justice for _____specially appointed under the Lunacy Act, 1890, upon the petition of (*Name of Petitioner*)_____
of (*Address and Description*)_____
in the matter of (*Name of Patient*)_____
a person of unsound mind, accompanied by the Medical Certificates of (A)_____and (A)_____ hereto annexed, and upon the undertaking of the said (*Name of Petitioner*)_____to visit the said (*Name of Patient*)_____personally or by someone specially appointed by the said (*Name of Petitioner*)_____
once at least in every Six Months while under care and treatment under this Order, hereby authorise you to receive the said (*Name of Patient*) _____as a Patient into your Hospital.
And I declare that I have [or have not] personally seen the said (*Name of Patient*)_____before making this Order.

(A) Names of Medical Practitioners signing Certificates.

Dated_____
Signed,_____ *Judge of the County Court of*_____
_____ or *Stipendiary Magistrate,*
To the _____ or *a Justice for*____ *appointed*
Resident Physician, *under the said Act.*
_____,

N.B.—*Under all circumstances, if possible, the "PETITION" and "STATEMENT" below to be filled up by the Patient's Relatives. If no Relatives, by the nearest Friend.*

PETITION FOR AN ORDER FOR RECEPTION OF A PRIVATE PATIENT.

In the matter of (A)_____ (A) Name of Patient in full.
a person alleged to be of unsound mind.
To His Honour the Judge of the County Court of _____
or To_____Stipendiary Magistrate for_____
or To_____a Justice of the Peace for_____
The Petition of (B)_____ (B) Name of Petitioner in full.
of (1)_____
in the County of_____
1.—I am (2) _____years of age.
2.—I desire to obtain an Order for the reception of (*Name of Patient in full*)_____as a person of unsound mind in_____

(1) Full Postal Address, and Rank, Profession, or Occupation.
(2) At least twenty-one.

3.—I last saw the said (*Name of Patient in full*)_____
at_____on the (3)_____day of_____189 .

(3) Some day before the date of the presentation of the Petition.

(4) Here state the connection or relationship with the Patient.

4.—I am the (4)_____of the said (*Name of Patient in full*)_____

If the Petitioner is not connected with or related to the patient, state as follows:—

I am not related to or connected with the said (*Name of Patient in full*)_____

The reasons why this Petition is not presented by a relation or connection are as follows:—

_____

_____

_____

The circumstances under which this Petition is presented by me are as follows:_____

_____

5.—I am not related to or connected with either of the persons signing the Certificates which accompany this Petition as—

(*where the petitioner is a man*) husband, father, father-in-law, son, son-in-law, brother, brother-in-law, partner, or assistant;

(*or where the petitioner is a woman*) wife, mother, mother-in-law, daughter, daughter-in-law, sister, sister-in-law, partner, or assistant.

6.—I undertake to visit the said (*Name of Patient in full*)_____ personally, or by some one specially appointed by me, at least once in every Six Months while under care and treatment under the Order to be made on this Petition.

7.—A Statement of Particulars relating to the said (*Name of Patient in full*)_____ accompanies this Petition.

If it is the fact, add—

8.—The said (*Name of Patient in full*)_____ has been received in the_____under an Urgency Order, dated the (5)_____

(5) Here insert date of Urgency Order, if any.

The Petitioner therefore prays that an Order may be made in accordance with the foregoing Statement.

*Full Christian and Surname of Petitioner*_____

Dated_____

N.B.—If neither of the Practitioners signing the Medical Certificates be the usual Medical Attendant of the Patient, the reason of this must be stated in writing to the Judge, Magistrate, or Justice by the Petitioner.

N.B.—Medical Certificates of Patient's Examination, and the Signatures, are required by the above Statute to be dated *not more than Seven clear Days* previously to the date of the presentation of the Petition.

Medical Practitioners signing the Certificates must not be in Partnership, nor one the Assistant of the other; nor must they be related to one another, as father, father-in-law, mother, mother-in-law, son, son-in-law, daughter, daughter-in-law, brother, brother-in-law, sister, sister-in-law, partner, or assistant; nor must they themselves sign the Petition or Urgency Order, nor must they be related to the Petitioner in any of the ways specified in the Petition.

One of the Certificates shall, *whenever practicable*, be under the hand of the usual Medical Attendant, if any (being a medical practitioner), of the alleged lunatic. They must use the terms specified in the Statute. (*See* marginal notes.)

By Order of the Commissioners in Lunacy.

1.—It is absolutely necessary that the Medical Men should write their Certificates legibly, so as to afford the opportunity of an exact copy being made.

2.—"All alterations in the original Certificates, *unless by the certifying Medical Men*, invalidate them; and *the initials of the latter* must be placed to every change or addition made."

CERTIFICATE OF MEDICAL PRACTITIONER.—Schedule 2, Form 8.

In the matter of (*Name of Patient*)_____

(1) of_____ in the_____ (2) of_____

(3)_____ an alleged lunatic.

I, the undersigned (*Name of Practitioner*)_____

do hereby certify as follows:—

(1) *Insert* RESIDENCE *of Patient.*

(2) *County, City, or Borough, as the case may be.*

(3) *Insert* PROFESSION *or* OCCUPATION *(if any).*

1. I am a person registered under the Medical Act, 1858, and I am in the actual practice of the medical profession.

2. On the_____ day of_____, 189 , at (4)_____ in the (5)_____ of_____, separately from any other practitioner, I personally examined the said (*Name of Patient*)_____ and came to the conclusion that he is a person of unsound mind, and a proper person to be taken charge of and detained under care and treatment.

(4) *Insert* PLACE *of examination, giving the* NAME *of the street, with* NUMBER *or* NAME *of the house, or should there be no number, the* CHRISTIAN *and* SURNAME *of Occupier.*

(5) *County, City, or Borough, as the case may be.*

3. I formed this conclusion on the following grounds, viz.:—

(*a*) Facts indicating Insanity observed by myself at the time of examination (6), viz.:—

_____

_____

_____

_____

_____

(6) *If the same or other* FACTS *were observed previous to the time of examination, the certifier is at liberty to subjoin them in a separate paragraph.*

(*b*) Facts communicated by others, viz.:—(7) (State the NAME IN FULL of the person giving the information, with the address and description.)

_____

_____

_____

(7) *The* NAMES *and* CHRISTIAN NAMES *(if known) of informants to be given, with their* ADDRESSES *and* DESCRIPTIONS.

4. The said (*Name of Patient*)_____ appeared to me to be (*or* not to be) in a fit condition of bodily health to be removed to_____.

5. I give this Certificate, having first read the Section of the Act of Parliament printed below.

Dated_____189 . Signed,_____

Full Postal Address_____

Extract from Section 317 of the Lunacy Act, 1890.

"Any person who makes a wilful misstatement of any material fact in any Medical or other Certificate, or in any Statement or Report of bodily or mental condition under this Act, shall be guilty of a misdemeanour."

N.B.—By Section 28, "Every Medical Certificate made under and for the purposes of this Act, shall be evidence of the facts therein appearing, and of the judgment therein stated to have been formed by the Certifying Medical Practitioners on such facts, as if the matters therein appearing *had been verified on oath.*"

In signing certificates it is well to remember that the most important points are the facts observed by one's self, and these facts bear much greater weight if they can be shown in brief to be associated with a development of nervous disturbance. Thus sleeplessness, restlessness, refusal to take food, threats of suicide, and a tendency to wander from home, would quite suffice without the additional fact which may have been communicated by A—B—, the nurse, that the patient tried to throw herself from the window, and said she was possessed by the devil. Whenever the certificate is strengthened by the addition of facts communicated by others, the name in full of such person must not be omitted. Certificates in England only hold while the patient is in England, and are broken by escape to the Continent, to Scotland, or to Ireland; but if a patient escape from an asylum, and remain in England, the same certificates hold good for fourteen days, during which period he may be recaptured.

Licenses for the reception of more than one lunatic into a private house are granted in the neighbourhood of London by the Commissioners, and in other parts of England by the magistrates in quarter session. Patients under certificates are in direct relationship to the Commissioners, who require a complete copy of the certificates upon which they have been received, as well as a statement within a week of the reception of the patient as to his bodily and mental condition. They also require that a medical visitation book of a prescribed form should be kept and entries made from time to time of the visits paid by some independent medical man to the patient. The frequency of these visits will be decided upon by the Commissioners themselves. All letters written by the patients to the Commissioners in Lunacy must be forwarded unopened; all other letters of patients must either be forwarded to their address, or, being initialled, must be kept for the inspection of the Commissioners on their visit, or of some other constituted authority.

Patients can be transferred from a private asylum into a private house, or from a hospital to a private house, or the reverse, permission having been sought and granted by the Commissioners in Lunacy. When a patient is sent from one establishment to another, the order of the Commissioners, with a copy of the original order, statement, and certificates, must be forwarded with him. Patients cannot be transferred from a private asylum or private care to a county or borough asylum, or the reverse.

Though a patient is of unsound mind and under certificates, his friends and relatives have no right to transact any business in his name unless a power of attorney have been previously granted by the patient; so that it is advisable in all cases where recurrences of insanity occur, or where the patient is sufficiently sensible to understand the threatening illness, to get a power of attorney before he loses self-control. This may save great trouble and expense afterwards.

If it be necessary to transact important business connected with a person of unsound mind, the only legal method is to place the affairs in Chancery, there being a special department of the Court for the purpose. Of Chancery cases there are two groups. The first includes only small properties, that is, under £2000 capital or £100 a year income, and for these the procedure is simple and rapid. It is as follows:—Two affidavits have to be drawn up in a form to be presently referred to, stating in detail the facts of the patient's insanity and his inability to transact business. These affidavits having been laid before the judge in Chancery, with certain other facts as to his affairs and his relations, by the family solicitor, an order may be given by

the Court of Chancery for the administration of this small estate; and two people, respectively called the committee of the person and the committee of the estate, will be appointed.

The following is an epitome of the second and longer process, which is costly and difficult to set aside, and therefore not to be undertaken without grave consideration: for the Court of Chancery will almost certainly realise the property of the patient, and a man's property may be realised at a very great loss while he is of unsound mind. It is therefore best to avoid placing any acute and presumably curable case under the Court of Chancery. When, however, it is necessary to put the affairs of a patient under the care of the Court, the family solicitor generally asks the medical man in charge of the case, or the asylum superintendent, to make a draft affidavit, and he also probably gets some independent medical expert in lunacy to draw up a second affidavit. These affidavits differ entirely from the ordinary medical certificate, there being no restriction as to consultation or separate and independent examination of the patient, and it is best to fill the affidavit up in the following way:—First, state your name, your medical qualifications, your qualifications to judge of the sanity of the patient, more especially your opportunities of having seen him; then give your judgment as to the form of disease from which he is suffering; give in the next two or three paragraphs a statement as to his general behaviour, his intellectual capacity, the delusions from which he suffers, the tendencies to suicide or destructiveness which he may have, and finally, give your judgment as to the improbability of his speedy recovery; or, if you believe him to be fatally or incurably insane, give your judgment that he is so and is unfit to take care, first of himself, second of his affairs. These two affidavits having been presented, in due course notice will be given to the patient that an inquiry or so-called inquisition or commission in lunacy will be held. The patient may then instruct counsel himself or he may demand to be tried by jury and to be defended by counsel and to be present himself. Or he may demand that he may be tried before a Master in Lunacy before a special jury. In one case at least a judge of the Court of Chancery took the position of the Master in an inquiry. In some cases where the patient is extremely suspicious, there may be considerable difficulty in persuading a jury that he is of unsound mind; and in nearly all cases where there is likely to be opposition of this kind, where in fact the patient is still so reasonable as to be able to defend himself, it is better to take any other means that are possible. If the patient be found insane by inquisition, the Court of Chancery in due time appoints one person to look after the affairs of the patient, who is called the committee of the estate, and another to look after the person of the lunatic, who is called the committee of the person.*

A Chancery lunatic remains so though he travel or though he escape to the Continent; he can be transferred from one asylum to another or from an asylum to a private house without any order of transfer from the Commissioners, all that is required being a signed order from the Court of Chancery and the committee of the person.

If a patient recover after he has been made a Chancery patient, it is necessary, before he can have his freedom and control of his property, that the whole of the proceedings should be set aside by a similar process. Two

* In future, after an inquisition, it may be decided that a patient is fit to be at large, but is not fit to manage his affairs.

medical men (preferably those two who have signed the first affidavits for the reception of the patient) should draw up two affidavits, this time stating their belief and the grounds for their belief that the patient is restored to his mind and is now fit to manage himself and his affairs.

The county and borough asylums are intended only for pauper lunatics, but really a large number of patients have to pass from private care to these county asylums because their friends are unable to pay the charges, which range from one guinea per week to almost any sum. Therefore chronic patients have to be provided for by the parish, the friends being called upon to pay for their maintenance in proportion to their ability and to the cost in the asylum. A certain number of county asylums at present receive paying private patients for sums under one pound a week, and it is arranged by recent lunacy legislation that all county and borough asylums may now receive such paying patients. Patients may, under certain conditions, place themselves in registered hospitals or private asylums as voluntary boarders.

IDIOCY AND IMBECILITY.—These two are but grades of the same want of intellectual development, "idiocy" ranging from almost complete absence of intelligence, whereas "imbecility" may approach very nearly to mere eccentricity and oddness.

Idiocy depends in the majority of cases upon structural defect in the brain. A certain number of idiots are the offspring of insane parents; certain others owe their condition to injuries received in early childhood; while certain forms of physical and mental disorder occurring in weakly or nervous children may arrest mental development at a higher or lower point, leaving as the result an idiot or an imbecile. The brain is so delicately constructed that a slight damage done to it during its period of growth interferes with its permanent and normal development.

In looking at the pathology of idiocy, we have to recognise the fact that some children are born with defective brains, so that in some there is very little more than the ganglia at the base: a brain which suffices for the nutrition of the body, but is unequal to the development of the mental functions. In other cases important parts of the brain are absent, its commissural fibres or the radiating fibres being deficient; and in the same category are to be considered the changes produced in the brain by defect of one or more of the senses. The child who comes into the world without sight and without hearing stands a very great chance of being an idiot through the consequent starvation of the brain. In idiots with defective brains we meet with every shade, from the anencephalous idiot, whose brain weighs but a few ounces, to the hydrocephalic idiot, whose brain is deficient though his head is enormous. In certain idiots there is rather a general deficiency than non-development of any one part of brain. All parts are there, but they are not sufficient. The convolutions are found to be broad and few, the grey matter is either not fully developed or is defective in quantity, or there is an enormous overgrowth of the connective tissue, so that in some idiots there are not only enormous heads but weighty brains. Beside all these, there are some children who in aspect are healthy, but who are idiotic or imbecile in consequence of some ill-understood defect in the power of the brain to work. If one may use the term, there are some "functional" or "neurotic idiots" who have fairly sized brains with fairly developed convolutions, and yet with inability to make

use of the brain they have. Some of these belong to the nervous stock generally, and others seem to have had their capacity for intellectual development arrested by some acute disorder of infancy. It is a question whether intermarriage will produce such cases.

The case of the so-called cretinous idiots will be considered in a separate chapter (*infra*, p. 859), and it is therefore unnecessary to describe the theories of the development of idiocy from arrest of growth in the base of the skull.

Most idiots are short-lived, many are defective not only in mind but in body. Many of them have malformations of limbs or a peculiar stunted aspect, with awkward, ungainly walk. Most of them are restless and irritable. Although generally slow of comprehension and dull as far as education is concerned, yet there are a certain number of so-called *idiots-savants* in whom some special faculty of the mind seems to grow at the expense of all the rest. Just as one may meet with a morally imbecile or morally insane person with certain intellectual activities fully developed, so in the learned idiot one may meet musical, mathematical, or mnemonic ability of a very high order.

Idiots have been divided according to their *capacity for speech*, the very lowest being unable to speak, the next group being able to articulate or make use of simple words, a higher grade being able to comprehend short sentences; while the lowest imbecile, somewhat in advance of the highest idiot, would have still greater power, and a higher imbecile would be able to learn and repeat many things, slowly perhaps, but yet surely. Other varieties have been based on the *facial peculiarities*; some idiots having extraordinarily receding foreheads have been compared to fish, and others have the aspect of a Chinaman, while some seem to resemble other races or even some of the lower animals; and when one takes up a book in which the physiognomy of man is compared with the physiognomy of brutes, one is struck with the examples which have evidently been taken in many cases from idiots and imbeciles.*

For our convenience here it will be well to take the groups of idiots as arranged by Dr Ireland. He makes ten groups—(1) Genetous idiocy; (2) microcephalic idiocy; (3) eclampsic idiocy; (4) epileptic idiocy; (5) hydrocephalic idiocy; (6) paralytic idiocy; (7) cretinism; (8) traumatic idiocy; (9) inflammatory idiocy; (10) idiocy of deprivation.

(*a*) *Congenital idiocy.*—The first class contains those cases which start in fœtal life; there is general weakness as a rule, mental and bodily, and the prospect is altogether unfavourable. The same holds good to a great extent with the microcephalic idiot, whose head, according to Dr Ireland, should measure less than seventeen inches; there being a distinct and absolute want of brain the prospect here is bad. In the third class of eclampsic idiots are placed those children who have ceased to develop in consequence of convulsions which have occurred during early childhood. Probably, however, a very large proportion of these come of a nervous stock, and are thus already unstable when some such exciting cause as teething suffices to start convulsions which so modify the brain in its development that it never assumes full vigour. Some of these cases may be trained to simple mechanical work.

* 'De Humana Physiognomia,' Joannis Baptistæ Portæ, Neapolitani, libri iv, ed. altera, Francofurti, 1618. Note particularly the figures of human faces resembling the ox and the pig (pp. 82 and 90). This principle of comparison was derived from Aristotle.

(*b*) The next is a nearly related group containing the *epileptics*. Fully one third of the idiots in the Metropolitan Idiot Asylum at Darenth are children whose idiocy is at all events accompanied by epilepsy. As a rule the epilepsy weakens both mind and body, and in many cases seems to be associated with great moral perversity, the epileptic idiot being hard to manage, and in very few cases suitable for home treatment. A certain number of epileptic idiots outgrow their epilepsy, and though mentally defective may be developed to a moderate intellectual standard. Such patients should be tried with bromide of potassium, but cautiously; food and fresh air with discipline and association with healthier children are the best forms of treatment.

(*c*) With *hydrocephalus*, idiocy is not uncommon, and if the hydrocephalus be great it is almost certain that there will be intellectual defect; but the majority of cases with considerable hydrocephalic and mental weakness die, so that the number seen in a large idiot asylum is not great. A good many of these cases by careful treatment improve, and from idiots may be trained into the class of useful imbeciles, to a certain extent trustworthy, but having organic deficiency of brain which prevents them becoming more than useful drudges. Beside the hydrocephalic idiot, we have to recognise a group of *paralytic* idiots, in whom some local defect of brain occurring in early life has given rise to paralysis of one or more of the extremities, and has left a mental as well as a physical scar upon the brain. In these cases again we can expect but little improvement from treatment; the weakened limbs may be galvanised, friction and passive movements with baths may be used, and some power may be gained in them, just as some slight power may be gained in the faculties.

(*d*) The next group contains the *traumatic* idiot. A number of idiots are found to be males that are firstborn, and a certain number of others are found to have had injuries to their head during parturition, and it is therefore well to remember that the delicate brain, too severely pressed upon by a narrow pelvis, or interfered with unnecessarily or severely by instruments, may be so permanently injured that idiocy results. Injuries before birth, at birth, or soon after birth occurring to children, will frequently prevent development; and there is no doubt that falls and similar injuries in early infant life give rise to a considerable proportion of idiots. Many of these are rather imbecile than idiotic; for the brain, which ought under natural circumstances to have fully developed, has been so interfered with that it only develops partially, and with it the mental faculties also are impaired but not wanting.

(*e*) *Inflammatory* idiocy is very closely allied to the last group, but under this head have been placed the idiots with hypertrophy of the brain. Here there is excess of connective tissue which interferes with the proper development, or at all events the proper function of the grey matter. Beside these, there are also the cases in which some disease of the nose or ears has set up inflammatory changes about the base or sides of the brain and interfered with its general development in a more or less mechanical way. As might be expected, the grades of idiocy from this cause vary very considerably.

(*f*) The only other important group is that associated with *deprivation of the senses*. It is quite certain that among the lower orders a considerable amount of weak-mindedness was formerly, and to a certain extent is still, due to the want of special education for the deaf and dumb. Deaf and

dumb children if not specially educated will from the deprivation of external impressions be but partially developed, and in some cases this deficiency will be more marked than in others. In some, in fact, who would be weak-minded at the best, the additional restriction of their intellect by the want of communication with the outer world leaves them imbecile or idiotic.

The same thing is still more true of those who happen to have loss or impairment of more than one sense: to them the portals of knowledge are closed. Nevertheless if these patients are taken early and trained specially, a large amount of instruction may be given them, and great amelioration of their condition will occur.

Idiots, if in the lower grades, should almost always be sent away from home. If there are other children, the influence of the weak-minded child upon them is distinctly injurious.

CRETINISM,

ENDEMIC BRONCHOCELE, AND THEIR ALLIES

"La vallée sans soleil donne le crétin."—BALZAC.

"Quis tumidum guttur miratur in Alpibus."—JUVENAL.

Cretinism as an endemic form of idiocy—Its anatomy—Endemic bronchocele—Sporadic cretinism in England—Relation of goitre to cretinism—The cretinoid condition in adults (myxœdema)—The condition which follows removal of a bronchocele (cachexia strumipriva) in man—and the effects of removal of the thyroid in animals—Acromegaly.

THERE is a form of Idiocy, not described in the last chapter, which is constantly associated with remarkable peculiarities of cranial and bodily configuration. Its subjects have long been known as "cretins."* Their mental symptoms do not appear to differ from those of ordinary idiocy. As in that condition, there are all degrees of defect of intelligence, so that a Royal Commission on Cretinism which reported to the Sardinian Government in 1848, divided those affected into three classes, for which they proposed the names of "crétins," "semi-crétins," and "crétineux."

Endemic cretinism.—The most marked form of this curious disease occurs endemically in the Alps, and here cretins are well known to differ from ordinary idiots. They are seldom more than four feet and a half in height, and often below three feet. They have large brachycephalic heads. The features are broad and ugly; the eyes are wide apart; the nose is very flat at the root, and spreads out towards the alæ; the lips are thick; the mouth large, wide open, and allows the saliva to escape. The forehead and cheeks are wrinkled and the skin is coarse and rough. The hair comes low on the forehead and is thick and bristly. The chest is narrow, the belly large, and the limbs crooked. The hands are clumsy and broad, with short fingers. Cretins always look old, and one of twenty years is like one of forty.

The admirable investigations of Virchow have shown that all the peculiarities in the configuration of the cretin's skull and face are the result of premature ossification of the basilar process. In a cretinous fœtus he found complete synostosis of the basi-occipital and basi-sphenoid bones, with a continuous layer of diploë from one to the other, so that no trace of the original separation could be discovered. The basi- and pre-sphenoid bones were also fused together; but this is less important, because their union usually takes place soon after birth, whereas the basilar process and the sphenoid bone should remain separate until at

* Endemic cretinism is an exotic disease, and we therefore have no English word for it. The word is adopted from Switzerland by the French (as *crétin*) and by the Germans (as *Kreidling*). Its origin is uncertain: some would derive it from *chrétien* (in the sense of "innocent"); others from a Romansch word, *cretira*; and others from *creta* in allusion either to the chalky complexions of those who suffer from the disease (Littré) or to the calcareous formation of the districts where it prevails. The German name points decidedly to some connection with *Kreide* (creta, chalk).

least the fifteenth year. The premature completion of this "tribasilar synostosis" (as Virchow calls it) appears to be followed by the cessation of all further growth of the basis cranii in an antero-posterior direction. It also gives rise to a marked deformity in the shape of the internal base, the most constant features of which seem to be that the sella turcica is very narrow, and that the parts in front of the posterior clinoid processes form a greater angle than normal with the clivus or basilar process. Virchow found that the slope of the clivus was unduly steep in one fœtus. But at an early age a steep clivus is normal; and Nièpce has stated that in the cretins whose bodies he examined this part was horizontal; an observation which receives confirmation from a dissection of the author's, to be presently referred to. It would therefore seem that the premature closure of the spheno-occipital suture, although it arrests growth, does not prevent some of the changes in the base of the cranium which should take place during childhood.

Laterally, the cretinous skull doubtless expands abnormally, so as to compensate for the deficiency in its antero-posterior diameter, and this gives to the features of the cretin their peculiar breadth. The sunken appearance of the root of the nose is probably due to deficient forward growth of the vomer.

The configuration of the head and face in cretinism is, then, directly attributable to premature synostosis of the basal sutures. Moreover, some of the peculiarities in the build of the rest of the body may possibly be due to a similar interruption in the growth of other bones. Thus, as Griesinger suggested, the shortening of the fingers and other parts of the limbs may depend on too early union of the epiphyses.

Endemic bronchocele.—The most important fact in the ætiology of cretinism is the very close relation which it holds to *endemic goitre*. In this country as well as in others, goitre prevails in districts in which endemic cretinism is not met with. Indeed, the only place in England where the latter disease has been observed is the village of Chiselborough in Somersetshire; and Dr Petherton, who in 1847 pointed out its presence there, told the author that it has since almost died out. On the other hand, there is probably no district in the world where endemic cretinism occurs without goitre being still more common. Moreover, it has been noticed that when a family migrates into a place where both diseases are met with, goitre is the first to appear; it is only in the second or third generation that cretins present themselves. These facts seem to point to the conclusion that both diseases depend upon a common cause, but that goitre results where it has acted for a shorter time or with less intensity, cretinism when it has acted for a longer time or with greater intensity.

Goitre or bronchocele is not a mere hypertrophy of the thyroid; it is a disease of that organ. If we except cysts and malignant growths and the remarkable disease known by the name of exophthalmic goitre (which will be described under diseases of the circulation), bronchocele is in most cases an endemic disease. Hence its association with cretinism.

Many cretins are also goitrous; but others, instead of possessing an enormous bronchocele, have no thyroid at all, and these are some of the worst. According to the Report of the Sardinian Commission, goitre is absent in one third of the cases of cretinism.

Sporadic cretinism.—It is a remarkable circumstance that in England a form of cretinism sometimes occurs which also bears a close relation to the thyroid, but which is not peculiar to one part of the country. In papers

in the 'Medico-Chirurgical Transactions' (1871) and the 'Pathological Transactions' (1874) the author originally described it as Sporadic Cretinism. In this form of the disease there seems never to be a large goitre; but in the case of a boy who came to Guy's Hospital from Halden, in Kent, a sister had goitre. In most cases the thyroid, so far from being enlarged, is entirely absent, and no trace of it can be discovered on dissection. This fact was first pointed out by Mr Curling in 1850. In most respects sporadic cretinism is identical with the endemic form of the disease. Some of the figures which illustrate the above communications on the subject (figs. 1 and 3, pl. iii, 'Med.-Chir. Trans.,' vol. liv, and fig. 2, pl. xii, 'Path. Trans.,' vol. xxv) show how close is the resemblance between the two diseases in their general characters. Among the patients affected with sporadic cretinism, one, at the age of sixteen years and a half, was only two feet eight inches high; another, when twenty years old, was only two feet four inches high. They have the same broad, square hands and short fingers, the same dry hair, the same rough scurfy skin. Their heads are large and broad; their noses are flat at the root, so that the distance between the eyes is increased; and their mouths are large and gaping, with thick lips.

In the only case in which an autopsy was made (through the kindness of Dr Grabham, of Earlswood) the base of the skull was much altered in shape; the posterior clinoid processes were at a higher level than the anterior, and the sella turcica was very narrow. The clivus was horizontal, and its position seemed to be part of a general elevation of the occipital in relation with the other bones, for the cerebellar fossæ were exceedingly shallow. The patient was twenty-one years old at the time of death.

The intelligence of those who are affected with sporadic cretinism is very imperfect, and many of them present an extreme degree of idiocy, so as to be deprived of the power of speech. Their disposition is generally mild and tranquil. In this respect they seem to differ from the subjects of the endemic disease; for Griesinger says that the latter are unsociable and repugnant to each other. Probably, however, much depends on the conditions under which such patients are placed, and the amount of care and interest bestowed upon them.

Dr Langdon Down has seen twelve and Dr Beach five cases. A typical one is described by Dr F. N. Manning, of Sydney, in the 'Trans. Med. Congr. of Australia,' 1889 (p. 834); and Dr Stirling (*ibid.*, p. 840) records six cases from South Australia, with characteristic photographs.

One of the most curious features of sporadic cretinism is the presence on each side of the neck in the "posterior triangle," outside the sterno-mastoid muscle, of a soft, lobulated, and moveable lipoma. A characteristic case of sporadic cretinism is figured by Dr Fletcher Beach in the 'Trans. Intern. Med. Congr.,' 1881, vol. iii, p. 627, in which there was no thyroid and two large supra-clavicular masses of fat. In one of the author's patients these supra-clavicular swellings were much larger than hens' eggs. Their size seems to be influenced to some extent by the state of the general health. In another case of Dr Beach's ('Path. Trans.,' xxv) they were well marked when the patient first came under observation, but disappeared entirely before death, which was caused by exhaustion after protracted diarrhœa.

These fatty tumours are sometimes found slightly developed in adults who otherwise appear to be in good health. They were very large and well marked in a man weighing fifteen stone, who consulted the writer in August, 1887, for obesity and symptoms of alcoholic excess.

We might expect the sporadic cases to throw light upon the obscure pathology of endemic cretinism. They do not, so far as is known, depend on any external cause. Dr Langdon Down suggested that it is due to alcoholic intoxication on the part of one of the parents at the time of procreation; but this hypothesis has been disproved. Cretinism has more than once been seen in several children of the same parents. Thus, in a family of twelve, three children were cretins of an extreme type, while the rest were healthy, and one was an accomplished oarsman; they were all born in London, and their parents were in comfortable circumstances. Another of the author's cases of sporadic cretinism was that of a girl, who was stated by her relations to have been perfectly healthy until she was eight years old, when she fell ill with what was supposed to be a second attack of measles, and kept her bed for a fortnight. After her recovery her physical development underwent a remarkable change. Her features were previously well formed; they now acquired the cretinous configuration. Her hair, once black and abundant, became light coloured, dry, crisp, and scanty. She ceased to grow; at the age of sixteen years and three quarters she was only four feet one inch in height. Her hands and feet were not larger than those of a child six or seven years old. She had a fatty tumour, the size of a hen's egg, above each clavicle; and no trace of the thyroid could be discovered in front of the trachea. Sporadic cretinism seldom develops itself so late as this, and endemic cretinism is probably always congenital. This case is very difficult of explanation. But taken with the fact that the thyroid is congenitally absent in so many cretins, it certainly suggests that the febrile illness at the age of eight years led in some way to atrophy of that organ, and this to supervention of the cretinous state.

Pathological relation of goitre and cretinism.—Deficiency of the thyroid has probably never been recorded except in cretins, and goitre is a real deficiency though an apparent increase of thyroid tissue, which may be compared to pseudo-hypertrophy of muscles, the bulky lungs of emphysema, and the large white kidney. There is, therefore, a close relation between the two conditions; but what the relation is, and on what common cause they both depend, are questions most difficult to decide.

With respect to goitre, it usually occurs in the valleys of a limestone formation; but drinking water impregnated with lime-salts, magnesia or ferrous sulphide cannot be its true cause. Cases are common, not only in the Alps and Pyrenees, but in Southern Germany, in the Peak district, where it is known as Derbyshire neck, and in mountainous regions in China, in the valleys of the Himalayas and of the Andes, and in other parts of the world. It does not occur endemically in hot, flat, or low-lying districts, or near the sea-coast.

Cretinism, as above stated, is far more restricted in range; but beside the sporadic cases above described, it occurs endemically in the goitrous regions of Switzerland, the Engadine, and the Tyrol; also in the Pyrenees, in Cashmere, and in Peru. It is found among the inhabitants of valleys, because the valleys are the parts inhabited; among those who drink snow-water, because snow-water is drunk among the mountains—for there are no cretins in the Arctic regions—and it is found among a goitrous population, because some unknown cause produces both diseases.

Two views may be taken of the relation of cretinism and goitre. One was put forward by the author of this work in 1871, namely, that they are both antagonistic effects of the same cause, and that goitre is protective

against cretinism; that when the cause begins to act, or acts with but little intensity, the sole effect is goitre; but that if it acts with great intensity, or upon successive generations, it at length produces cretinism as well as goitre. The not infrequent absence of goitre in cretins—when not dependent upon congenital deficiency of the thyroid—might then be attributable to some local morbid change in that organ, by which it is prevented from enlarging as usual under the stimulus of the unknown morbid cause. It is conceivable that when goitre has existed in a family for two or three generations, the structure of the thyroid may undergo deterioration in some of the succeeding generation; and the likelihood of the occurrence of such a local degeneration is perhaps augmented by the consideration that all families in which advanced cretinism is prevalent tend to undergo complete extinction within a very few years. According to the Sardinian Commission it is rare for any family residing in the Valpelline to reach a fifth generation. If it were not for immigration into this valley it would become altogether depopulated. Such a deterioration of structure in the thyroid would of course favour still more the development of cretinism, according to the theory suggested. Large goitres are frequently present in the non-cretinous brothers and sisters of those cretins who themselves have no goitres, or only small ones.

The other explanation of the relation between goitre and cretinism is that they are not antagonistic, but consecutive effects of the same unknown cause; that endemic goitre is not a true hypertrophy, but a degeneration of the thyroid, and that although a local disease, yet when inherited, or when supervening early, or when, most of all, the thyroid is congenitally absent, it produces more widely spread and serious disturbance so as to affect the nutrition of the whole body. We shall presently see that this view is supported by the results of experimental and surgical removal of the thyroid. But before mentioning this artificial cretinism it will be well to describe an allied condition, not endemic but sporadic, not congenital but acquired, and sometimes not developed till long after adult life is reached.

CRETINOID CONDITION IN ADULTS.*—Sir William Gull first described in 1873 ('Trans. Clin. Soc.,' vol. vii) a very remarkable condition which he termed *cretinoid*, and which occurs in adults—most frequently in adult women. It is characterised by a change in the features, which become broad and flattened; the eyes appear too wide apart, the alæ nasi become thick, the lips large, the connective tissue below the eyes loose and baggy, and that under the jaws and in the neck thick, and thrown into folds. The tongue is so large as to embarrass articulation, and interfere with wearing false teeth. The hands are broad and "spade-like." The texture of the skin becomes smooth and the hairs thin and scanty, while individually they are thicker and coarser than before. The general hue is pale, sometimes of a dirty white, recalling that of the cachexia caused by malaria, by syphilis, or by lead, sometimes of a clear lemon-yellow like that of Addison's anæmia; but the cheeks are most commonly rosy, not only from dilated veins, but with a diffused purple which looks like rouge. At the same time the disposition of the patient undergoes an alteration, activity of mind giving place to a gentle placid indifference.

* "A cretinoid state supervening in adult life in women (Gull)."—*Synonyms.*—Myxœdema (Ord), Cachéxie pachydermique (Charcot), Cachexia strumipriva (Kocher), Myxœdème primitive et opératoire (Reverdin)—Acquired or adult cretinism.

A striking case of this malady was under the writer's care in Mary Ward (1885). She had the coarse scanty hair, the sallow complexion, with spots of bright red on the cheeks, looking as if she painted, the subconjunctival œdema, the broad, clumsy hands, thick blubber lips, slowness in answering, and tranquil temper. The contrast with a photograph taken ten years before was most remarkable. Though the "bladders" under the eyes looked ready to burst, acupuncture failed to bring out a drop of serum. Another woman was in another division of the same ward under Dr Taylor, and the resemblance of the two was remarkable. In fact, the physiognomy when fully developed is unmistakable.

The year before (1884) there was a man in Philip Ward in an early stage of the same condition. His deliberate answers, heavy aspect, and placid ox-like demeanour were already characteristic. Afterwards œdema, spade-like hands, and the other features above described developed into a typical picture; so that, when he was subsequently in St. Thomas's Hospital, and was shown by Dr Stone at an examination (1887), every candidate recognised the disease at once, even though he had never seen a case.

The uniformity of aspect of this affection, whether occurring in women or more rarely in men, is not the least remarkable of its characters.

Many cases have been now recorded in England since Sir William Gull first drew attention to the subject; by Dr Ord ('Med.-Chir. Trans.,' 1878; 'Clin. Trans.,' xiii, 1880), Sir Dyce Duckworth ('Clin. Trans.,' xiii, 1880), Dr Cavafy (*ibid.*, xv, 1882), Dr John Harley ('Med.-Chir. Trans.,' 1884), Dr Drewitt ('Clin. Trans.,' xvii, 1884), Dr Nixon ('Dublin Quart. Journ.,' Jan. 1887). Cases have also been recognised in France; and in Germany by Riess, Erb, Senator, and Landau ('Berliner klin. Wochenschrift,' 1886, 1887). An elaborate report on 109 cases collected from various sources was published by the Clinical Society as an appendix to the 21st volume, and forms the most complete account of the disease that exists.

The pathology and causes of this disease are quite unknown. It differs from the sporadic cretinism above described in the absence of deformity of the bones, and in the slight degree in which the mind is affected; both these differences probably depend upon its late development. But it seems probable that it depends on the same essential cause, and differs chiefly from the fact that this operates when the stature, the ossification of the bones, and the mental faculties are already fully developed.

The late Dr Mahomed at one time believed that these patients were only examples of chronic Bright's disease; in many cases there is certainly albuminuria, and in some the other signs of granular degeneration of the kidneys, but in others equally marked the urine is perfectly normal. The apparent œdema is not ordinary anasarca, for serum does not exude on puncturing the skin. In a patient who died at St Thomas's Hospital Dr C. Charles found excess of mucin in the œdematous tissues after death; accordingly the name "myxœdema" has been proposed by Dr Ord for this remarkable cretinoid condition in adults. But the condition which suggested it is not constant, for no excess of mucin has been found when sought for in other cases ('Clin. Soc. Report,' 1888, pp. 47—54).

Artificial cretinism.—Before myxœdema was recognised on the Continent, a remarkable condition which has been called "cachexia strumipriva"* was observed as the result of extirpation of bronchocele by Swiss

* *Struma*, as the equivalent of *scrofula*, meant originally a swollen neck, and was long applied indifferently to goitre and to swollen cervical lymph-glands. In Germany it has been restricted to the former meaning, so that struma means a bronchocele.

surgeons, Dr Reverdin, of Geneva, and Dr Kocher, of Berne. After some months the patients who have survived the operation begin to show mental hebetude, pallor, œdema, and some other of the characters of an adult cretin ('Arch. f. kl. Chir.,' 1883, p. 254).

In the following year Schiff, Wagner, and Sanquirico successfully removed the thyroid in dogs, and found that the operation was followed by cerebral disturbance, tremors, and convulsions, at first clonic but then tetanic, ending in death by coma.

Mr Victor Horsley has repeated these experiments on monkeys ("The Brown Lectures," reported in the 'Brit. Med. Journ.,' Jan., 1885). He finds that (usually within a week) after the operation, fibrillary tremors appear in the limbs, which, like those of paralysis agitans, cease on voluntary movement. The monkey becomes anæmic, with increase of leucocytes as well as diminution of red discs. It sits moping and imbecile. The eyelids and abdomen swell. The temperature falls below normal, all tremors disappear, and the animal dies comatose in five to seven weeks. Two remarkable conditions appear to justify the application of the word myxœdema. One is great swelling of the submaxillary and parotid glands, so that the latter become as it were transformed into muciparous glands; and the other is the great increase of mucin in the connective tissues, especially the tendons and superficial fascia, and its appearance in traces in the blood. These facts rest upon analyses made by Dr Halliburton. Similar experiments have been carried out by Professor Welch, of Baltimore ('New York Medical Record,' 1888, p. 368).

Certainly the agreement of these results with those observed in human beings after thyroidectomy, and of both with the cretinoid condition of Sir William Gull and with sporadic and endemic cretinism itself, are very remarkable, and support the view above taken of the relations between cretinism and goitre.

Acromegalia.—A remarkable case resembling myxœdema occurred in a patient of Dr Wilks, a young lady who was at one time not unpleasing in appearance. Her features underwent a most extraordinary change, and she became so hideous that the boys shouted at her when she showed herself in the streets. Her face became elongated; and her nose, lips, and mouth were enormous. There was not the slightest infiltration or hardening of the skin or subcutaneous tissue. She gradually became blind, and had suffered from neuralgia. Her hands could not be fitted with ordinary gloves. She died after six years, "comatose," but at a distance from town, so that there was no autopsy. The urine did not contain albumen. This (Dr Wilks informs the writer) was certainly an example of what was described by Mons. Pierre Marin in 1886 as *Acromegalie.*

About fifteen cases of this disease have been recorded. The hands, feet, and face become hypertrophied and deformed; the bones and skin are the chief seats of the disorder, which might be confounded with myxœdema or with elephantiasis. A monograph by Erb was published in the 'Deutsche med. Zeitung' for Oct., 1887; and cases by Dr Haddon and Mr Ballance and by Mr Godlee ('Clin. Trans.,' xviii and xxi, 196, 201) in 1888. There is sometimes disease of the thyroid and sometimes hypertrophy of the pituitarium; but the latter condition is not constant. There are as many cases in men as in women.

DISEASES OF THE RESPIRATORY SYSTEM

AFFECTIONS OF THE LARYNX AND TRACHEA

"Sputaque per fauces raucas vix edita tussi."—LUCRETIUS.

The laryngoscope and its use—Arrangement of the subjects of this chapter.

LARYNGEAL PARALYSIS—*Of one or both recurrent nerves—Of the abductor muscles alone—Of the adductors—Aphonia and other disorders of the voice.*

LARYNGISMUS STRIDULUS — *Nomenclature — Symptoms and Diagnosis—Pathology—Ætiology—Prognosis and treatment.*

LARYNGITIS—*Acute plastic inflammation—Croup—Its relation to Diphtheria and to Spurious Croup—Its symptoms and causes, anatomy, diagnosis, and treatment—Acute and chronic catarrh of the larynx—Tubercle—Lupus—Syphilis of the larynx—Œdematous laryngitis—Perichondritis.*

TUMOURS OF THE LARYNX—*Papilloma—Polypus, &c.—Sarcoma and Carcinoma—Laryngeal malformations—Foreign bodies in the larynx.*

OBSTRUCTION OF THE TRACHEA—*External compression from enlarged thyroid, aneurysm, &c.—Intrinsic stenosis from syphilis, &c.—Obstruction by impaction of a foreign body—Symptoms, diagnosis, and treatment.*

THE diseases of the larynx, like those of the retina, have within recent times been made accessible, as they never were before, to actual inspection. This is entirely due to the invention of a special instrument—the *laryngoscope*—which was first introduced into medical practice in Vienna by Türck and by Czermak. Türck, in the summer of 1857, began to examine his hospital patients with a laryngeal mirror, such as had been used in physiological researches a few years before by Manuel Garcia, a singing-master, in London, who read a paper on the voice before the Royal Society. Even this was not the first effort to see the interior of the larynx in the living subject, for it had been attempted, though with but little success, by several other observers, including the younger Dr Babington in 1829 and Mr Avery in 1844. Türck suspended his operations in the winter of 1857–8 for want of sunlight, and he lent his mirrors to Czermak, who, setting to work with artificial illumination, became convinced of the extreme value of laryngoscopy for clinical purposes, and after publishing a paper on the subject in March, 1858, in the 'Wiener medicinische Wochenschrift,' travelled over Germany, France, and England, to make it more widely known. He gave demonstrations on his own larynx by direct sunlight at Guy's Hospital in 1859.

The laryngoscope is now in the hands of every practitioner. In using it, the first thing is to secure a bright light, whether from an Argand gas-burner, an oil lamp, or the sun itself. The patient is placed with his back

to the source of illumination, the rays from which pass over his shoulder. The observer seats himself opposite, on a chair slightly more raised, and throws the light upon the lower part of the patient's face by means of a flat or slightly concave mirror, either held in one hand, or, when both are needed, fixed on a band round the head, by a handle held in the mouth or in a spectacle frame made for the purpose. The patient is next made to open his mouth and to protrude his tongue; and this is gently grasped by the patient himself with his thumb and forefinger in the folds of a napkin, so as to leave both the observer's hands free. In some patients the tongue is an unruly member, and the only plan may be to keep it depressed with a spatula bent at a right angle. The light is thrown into the back of the fauces, and kept steadily fixed there. In the meantime a stalked laryngeal mirror is warmed over a flame, or in hot water, or it may be smeared with glycerine; the object being to prevent its surface becoming dimmed by the moisture of the breath. The patient is now instructed to go on breathing quietly and regularly, and to sound an "a" (as in fate) on rather a high note. This brings the fauces into a position advantageous for the introduction of the laryngeal mirror, which is held like a pen between the finger and thumb, and gently but rapidly passed through the patient's mouth until it reaches the uvula, while the stem lies at the angle of the mouth, so as not to interfere with the entrance of light. The observer should learn to use the laryngeal mirror with the left hand, so as to have the right hand disengaged. In traversing the mouth the instrument must have its face turned downward, and it must take a curved course, being kept close to the palate and as far as possible from the tongue. As it reaches the uvula it must be tilted, so that its face looks forwards as well as downwards. It must also be gently pushed upwards and backwards, lifting the uvula and the velum. While this is being done the back of the tongue, the epiglottis, and the interior of the larynx successively become visible, reflected in the mirror. If this is not the case, slight changes in its position or inclination generally bring them into view. As a rule it should not be carried so far back as to touch the posterior wall of the pharynx, which in many patients is far more sensitive than the velum, but some persons bear the mirror perfectly well, even when it is made to rest on the pharyngeal surface. There is seldom any necessity, so far as purposes of diagnosis are concerned, for continuing a single observation for more than a very short time. Should the interior of the larynx not be completely visible, it is best to withdraw the instrument and reintroduce it a minute or two later.

It may well be supposed that the practical use of the laryngoscope is in some cases attended with difficulties. In this matter, as in all others, habit goes a long way. The student finds himself at first baffled, and fails to see anything, whereas the trained observer succeeds at the first attempt; and the patient who when the mirror is first introduced in his mouth thinks he cannot tolerate its presence, becomes after a few trials indifferent. One trouble is with the tongue, which in some persons arches upwards so as to interfere not only with the passage of the mirror, but also with the admission of light to the back of the throat. They must then be directed to practise before a looking-glass until they can "make a wide throat." Or the spatula must be used. Another obstacle is the presence of enlarged tonsils narrowing the faucial space. This is best overcome by using a small mirror. In some patients, again, the uvula and the velum are so irritable that the slightest contact of the mirror causes choking, or retching, or

cough. Sir Morell Mackenzie recommends that to meet this difficulty small pieces of ice should be sucked for fifteen or twenty minutes before the laryngoscopic examination is begun; this, he says, rarely if ever fails to blunt for a time the sensitiveness of the mucous membrane. The best method, however, of securing anæsthesia is to apply cucaine locally. A 20 per cent. solution brushed over the part, or, still better, applied as a spray, will after a few minutes enable one to examine the most sensitive patient. The alkaline bromides taken in a full dose half an hour previously produce more or less anæsthesia of the fauces.

In some patients, who have affections of the throat or lungs, the introduction of the mirror seems at once to be followed by the entrance of a quantity of muco-purulent fluid into the fauces from below, notwithstanding the repeated use of a gargle. Or the uvula may be so long and pendulous that it curls round the under edge of the mirror, interfering with the view of the larynx, or soiling the reflecting surface. The way to correct this is to use a large mirror, so as to lift up the whole of the uvula. But the most serious difficulty of all is caused by a large epiglottis, which hangs backward over the entrance of the larynx in such a way as to prevent anything else being seen. In many cases this obstacle is easily removed by making the patient sound, or attempt to sound, the vowel *e* (as in *feet*) on a high note. The sound itself cannot actually be produced while the tongue is protruded, but Störk says that the effort to produce it is often sufficient to raise the epiglottis. Sometimes the interior of the larynx can be seen, in spite of a pendent epiglottis, if the mirror is placed rather lower in the fauces than usual and with a more vertical inclination of its surface, the patient's head being at the same time thrown far backwards. But it may happen that all these plans fail. An attempt may then be made to raise the epiglottis by a curved sound brought into contact with its posterior surface. In most persons the back surface of the epiglottis is so sensitive that a choking sensation is produced as soon as it is touched. But the use of the cucaine solution enables one to draw the epiglottis forward with the blunt hook in the left hand, guided by the mirror held in the right.

The parts reflected in a laryngeal mirror retain their proper positions so far as concerns the side of the body on which they seem to lie; the left vocal cord is visible upon the left side of the mirror, the right one upon the right side. But in an antero-posterior direction the image is inverted, as if one were looking at the larynx from behind instead of through the mouth. In other words, the base of the tongue and the epiglottis form the top of the laryngoscopic image, and the arytænoid cartilages are seen below.

The appearance of the epiglottis varies widely in different persons. Sometimes little more than the edge of it is seen, sometimes a large part of its posterior surface, which has normally a bright red colour, apt to be taken for morbid congestion. The rest of the laryngeal mucous membrane is of a paler tint, and the vocal cords are white and glistening.

Arrangement.—Most of the affections of the larynx interfere with the performance of both its functions, the formation of the voice and the passage of air into and out of the trachea; and many of them are also attended with other symptoms, as pain, tenderness, a peculiar cough, and dysphagia, as well as with varied and complicated laryngoscopic appearances. It therefore seems advisable to begin the description of laryngeal diseases with certain affections, of which some give rise only to an impairment or loss of

the voice, others only to interference with the breathing, the results of examination with the mirror being correspondingly simple and definite. These are the paralytic and the spasmodic affections of the muscles of the larynx. Although of secondary importance to the specialist, they possess peculiar interest for the physician from their bearing on diseases of distant structures. Their proper place is among the affections of the nerves or nervous centres, but for reasons of practical convenience it is desirable to take them with other affections of the larynx.

Different writers classify laryngeal paralyses in different ways. Störk first discusses affections of the several muscles one by one, as they may theoretically be imagined to occur; afterwards he passes to more complex forms, in which many muscles are involved together. Mackenzie arranges them according to their supposed seat in the bulb, in the trunks of the vagi, or in their laryngeal branches. For our present purpose it will be sufficient to describe such forms of paralysis as are recognisable in clinical practice, noting the muscle or muscles involved in each.

The spasmodic affections to which the laryngeal muscles are liable will follow, then the several forms of laryngitis, and the new growths of the organ. Lastly, the symptoms and diagnosis of obstruction of the larynx and trachea will be considered.

PARALYSIS OF ALL THE MUSCLES SUPPLIED BY THE RECURRENT LARYNGEAL NERVE OR NERVES.—Among the most frequent paralytic affections of the larynx, as might naturally be anticipated, is one which involves all the muscles supplied by the recurrent nerve either on one side or on both. This, when unilateral, is sometimes spoken of as "hemiplegia of the larynx." If a special name is wanted, it would be better to follow the analogy of the word ophthalmoplegia, invented by Mr Hutchinson for a general paralysis of all the muscles of the eyeball, and to speak of "laryngoplegia" when the muscles of both sides of the larynx are affected, and of "hemilaryngoplegia" when the paralysis is one-sided. The paralysis is not quite universal, since the crico-thyroid muscles must escape. But it does not appear that any appreciable physiological action results from their contraction when the other laryngeal muscles are powerless. Moreover, Türck has observed fatty degeneration and atrophy of the crico-thyroid muscle in a case in which the recurrent laryngeal nerve was alone affected, while the superior laryngeal nerve escaped.

It will be necessary to describe separately the effects of unilateral and of bilateral paralysis of the recurrent nerve.

1. *Unilateral paralysis of the recurrens* is characterised by complete immobility of the corresponding vocal cord, whether the patient only continues to breathe or utters a vocal sound. The position occupied by the cord is usually what is termed the "cadaveric position," the same as that assumed by the vocal cords in the dead body, when no muscular force any longer acts upon them—intermediate between phonation and inspiration. But sometimes the cord is drawn inwards to the middle line by the action of the arytænoideus. The outline of the cord looks concave. The summit of the arytænoid cartilage is placed a little further forwards and inwards than that of the opposite cartilage, so that it looks larger from more of its hinder surface being seen. When a sound is uttered, the opposite arytænoid cartilage moves further than usual, and the unaffected vocal cord is drawn up to and even across the middle line, until it may come close to the paralysed

one, and so the chink of the glottis become oblique. At the same time the summit of the mobile arytænoid cartilage crosses in front of the cartilage on the paralysed side. When paralysis has lasted a long time the affected cord may be seen to be obviously atrophied, and may oscillate backwards and forwards as the stream of air passes over it.

The voice of a patient with paralysis of one recurrent nerve is less altered than might have been expected. It is often weak and hoarse, and sometimes breaks into a falsetto as soon as an attempt is made to speak forcibly. A point to which Gerhardt has drawn attention is that when two fingers are placed, one on each side of the thyroid cartilage, while the patient is speaking, a more distinct vibration can be felt with one finger than with the other. There is not the slightest dyspnœa.

2. *Bilateral paralysis* of all the muscles supplied by the two recurrent nerves is characterised by immobility of both vocal cords in the cadaveric position. It is to be noted, however, that the paralysis is often less complete on one side than on the other.

There is complete aphonia, the voice being reduced to a whisper; and the patient is unable to cough or to expectorate forcibly. There is no dyspnœa, at least in adults.*

Diagnosis.—It must be borne in mind that immobility of the vocal cord, whether on one side or on both, is not in itself proof of paralysis. As Dr Semon pointed out in the 'Medical Times and Gazette' for 1880, precisely the same laryngoscopic appearances may be the result of ankylosis of the crico-arytænoid joints. This fact had, indeed, been recognised to some extent by previous writers, especially in Germany. But it seems to have been supposed that perichondritis, before leading to fixation of the joint, must almost of necessity be attended with suppuration. Dr Semon maintains that non-suppurative arytænoid synovitis may obliterate the synovial cavity, and unite the cartilages to one another. It is of course only when the arytænoid cartilages are so fixed as to bring the cords into the cadaveric position that the case can be taken for one of recurrent paralysis, and then, as Dr Semon admits, diagnosis is sometimes impossible.

Pathology.—The causes of paralysis of the muscles supplied by the recurrent nerve or nerves fall into two groups.

(1) There may be *central* disease of the nuclei of the nerves of the eighth pair, on one side or on both, in the pons; as in bulbar paralysis or multiple sclerosis. Such paralysis is usually bilateral and almost always secondary.

(2) The disease may be *peripheral*, interfering with the roots or trunks of the spinal accessory and pneumogastric nerves near the base of the skull, or with the trunk of the vagus after its separation from the spinal accessory or with the recurrent laryngeal branch. As a rule, the paralysis is in such cases unilateral. Indeed, by far the most frequent cause of paralysis of the muscles of one half of the larynx is aneurysm of the aorta, in which case the affection is most often on the left side. Aneurysm extending to the innominate artery may, however, compress the right recurrent nerve. Again, mediastinal growths of various kinds may interfere with the left nerve,

* This is a point about which there was at one time some divergence of opinion, but it seems now to have been finally settled. Scheck has recorded a case in a boy of seven, whose breathing was in no way interfered with. Ziemssen, however, still says that in deep inspiration the cords may be drawn a little further inwards than before, and that a stridulous sound may be produced.

while either the left one or the right may be pressed upon by an enlarged thyroid, or by cancerous tumours of the œsophagus or the vertebræ. These last-mentioned peripheral causes not infrequently affect each recurrent nerve in succession and produce bilateral paralysis. Mackenzie has published a case in which there were two aneurysms of different parts of the aorta, one of which compressed the right and the other the left recurrent nerve; and in 1866 Dr Bäumler recorded an interesting example of bilateral paralysis of the recurrent nerves, apparently due to the pressure of a large pericardial exudation.

It is a singular fact that peripheral interference with a single vagus sometimes causes precisely the same result. This was pointed out by Dr Bäumler in the 'Pathological Transactions' for 1872, and two years later Dr George Johnson made it the subject of an interesting paper in vol. lviii of the 'Med.-Chir. Trans.' The only possible explanation seems to be that ascending neuritis spreads to the bulb by the centripetal fibres of the affected vagus. If so a lesion involving only the recurrent nerve and not the vagus itself must be incapable of producing the same effect, as was well shown by Dr Semon in the 'Berl. klin. Wochenschrift' for 1883. The further spread from one lateral nucleus to the other may be explained by the existence of a close physiological connection between the nuclei of the two sides. But Lockhart Clarke further showed that some of the fibres of origin of the spinal accessory nerve (which include the root-fibres of the recurrent laryngeal) actually pass across the middle line, being derived from the opposite nucleus; so that it is not inconceivable that disturbance of a single nucleus may directly cause bilateral paralysis.

The paralysed muscles become atrophied, as was clearly shown in Dr Bäumler's case. Indeed, there is no form of paralysis in which the resulting muscular atrophy is more obvious on dissection than paralysis of the muscles supplied by the recurrent nerve. In unilateral cases, in particular, the contrast between the whitish-yellow, shrunken crico-arytænoideus posticus on the affected side and the red fleshy muscle opposite to it is more striking than any similar condition in other parts of the body. The recurrent nerve also, below the point at which it is compressed, is greatly wasted and of a dull grey colour.

The *prognosis* of recurrent paralysis depends upon its cause. In Bäumler's case, in which it was dependent upon exudation into the pericardium, the patient, whose voice had been reduced to a whisper, recovered quickly as the effusion underwent absorption; within four or five weeks from the time when he first became hoarse he could speak nearly as well as ever. As a rule, the primary disease is incurable, and the paralysis persists until death.

A goitre, if this is present, might be actively treated, but it is useless to prescribe strychnia or to apply galvanic or faradic currents.

PARALYSIS OF THE ABDUCTORS OF THE CORDS (THE CRICO-ARYTÆNOIDEI POSTICI).—Since recurrent paralysis is commonly the result of a morbid process gradually destroying the fibres of the nerve or the nucleus from which they arise, it is natural enough that cases should be met with in which some only of the muscles supplied by it suffer, while others escape. But it is a remarkable fact that such incomplete forms of paralysis invariably affect one particular pair of muscles, the *crico-arytænoidei postici* which widen the space between the cords on deep inspiration. Indeed, many cases have been recorded of paralysis of both recurrent laryngeal

nerves, and yet no muscle has been affected except the posterior crico-arytænoid on each side. Gerhardt published the first example of such an occurrence in 1863, and an admirable lecture on the subject by Riegel may be found in the second volume of 'German Clinical Lectures,' edited for the New Sydenham Society in 1877. The reason for this proclivity of the crico-arytænoid is still obscure. When there is a nuclear lesion in the bulb we may suppose that the nucleus for the fibres to the abductors is distinct from that for the other laryngeal muscles, just as we explain how in most cases of bulbar paralysis the lower part of the face is affected while the upper part escapes. But the result is just the same when the disease involves the upper part of the vagus or the recurrent nerve. It would seem that the fibres to the abductors undergo destruction earlier than those to the adductors. Indeed, Riegel actually found in one of his cases, in which both the recurrent nerves were embedded in dense connective tissue, that although the majority of the fibres had undergone fatty degeneration, some still retained their normal structure. During the meeting of the International Congress in London, in 1881, Rosenbach pointed out that in paralytic affections of the limbs there is an analogous fact in the greater liability of the extensors and abductors than of the adductors to suffer. Moreover, when the laryngeal muscles are affected with spasm, the abductors are invariably overpowered by the adductors. Possibly the innervation of the latter group of muscles is better than that of the former.

The laryngoscopic appearances which characterise paralysis of a *single abductor* are that the corresponding vocal cord lies more or less near the median line, and does not move outwards as it normally should when the patient takes a deep breath. On the other hand, during vocalization it moves freely inwards. Hence unless the state of the larynx is carefully inspected while the patient is not, as well as while he is, attempting to utter a sound, this affection will be overlooked.

When both abductor muscles are paralysed, the two cords lie nearer one another than they do in health. The degree to which they are approximated varies with the duration of the paralysis. In cases of long standing they may lie so close together that during inspiration it is scarcely possible to perceive the slightest chink between them; while during expiration they slightly recede from one another. Riegel argues that this extreme narrowing of the glottis is the result of a gradual contraction of the antagonists of the paralysed muscles, exactly analogous to that which occurs in motor paralysis of the eyeball, the face, or the limbs. But in a case recorded by Feith it seems to have come on only a few days after the paralysis.

Another factor in the production of such a very marked stenosis of the glottis during inspiration is in all probability a sucking in of the cords towards one another, in consequence of the diminution of atmospheric pressure upon their lower as compared with their upper surfaces.*

Apart from the results of a laryngoscopic examination, subjective symptoms of paralysis of a single crico-arytænoideus posticus are altogether want-

* In two cases seen by Dr Semon there was a modification of the usual laryngoscopic appearances; the cords were close together only along their anterior two thirds, and diverged posteriorly so as to leave a triangular opening with its base at the interarytænoid fold. It is suggested that this depends upon a limitation of the paralysis to the outer fibres of the crico-arytænoidei postici, their inner fibres escaping. Rühlman has, in fact, endeavoured to show that each of these muscles consists of two portions having different functions: the inner portions, he says, draw the arytænoid cartilages downwards and outwards upon the cricoid; the outer portions rotate the arytænoid cartilages upon their vertical axis.

ing. The patient's voice is of course perfect, and as there is plenty of room for the entrance of air, he experiences not the slightest dyspnœa, even on exertion. It is this fact which gives clinical importance to Dr Semon's observations of the invariable occurrence of paralysis of this muscle as the result of disease of the recurrent laryngeal, or of the vagus trunk or nucleus. He has shown that there are many cases of aneurysm, of mediastinal growth, of carcinoma of the œsophagus, and even of disease at the base of the brain, upon which a routine use of the laryngoscope throws as much light as does the routine use of the ophthalmoscope on cases of cerebral tumour or chronic Bright's disease.

When *both abductors* of the vocal cords are paralysed the symptoms may be of the most urgent and dangerous character. The voice is still unimpaired, unless there is a coincident imflammatory affection of the larynx. But there is often most distressing inspiratory dyspnœa, the air being slowly drawn into the chest with loud stridor, and the patient becoming livid, with cold extremities, and ultimately dying of suffocation. In such cases the laryngoscope is needed, not so much to distinguish the affection from other diseases of the larynx as from stenosis of the trachea.

The mere fact that during inspiration the cords are drawn close together near the middle line is not of itself proof that there is any paralysis of the abductors; there may be a spasmodic affection of the adductors. What marks the difference is the way in which the dyspnœa begins. A primary spasm is rapid in its development; the contraction of antagonists which obstruct the entrance of air in cases of paralysis of the abductors comes on slowly. At first there is difficulty of breathing only when the patient makes some effort or exertion; then it gradually becomes persistent and increases in severity.

With regard to the *causes* of paralysis of one or both of the abductor muscles of the cords, we have already seen it may be either central, or due to some affection involving the upper parts of the vagi, or the recurrent nerves in their course. In the 'Pathological Transactions' for 1882 a case is recorded by Dr Whipham, in which a bilateral paralysis of the abductors was dependent upon implication of the left pneumogastric and recurrent nerves in the walls of a thoracic aneurysm. In some cases this form of paralysis has followed diphtheria, and once it has been a sequela of facial erysipelas. It has been ascribed to exposure to cold; and Mackenzie thinks it may be due to direct pressure on the fibres of the crico-arytænoidei postici through the anterior wall of the pharynx in swallowing. Indeed, a case by Ott is cited, in which it was the result of a piece of meat being impacted for twenty-four hours at the opening of the œsophagus.

Prognosis and treatment.—In some cases recovery takes place after weeks or months, apparently independent of treatment. Much more often the affection remains incurable. Sometimes a large amount of relief to the subjective symptoms, with temporary disappearance of the attacks of dyspnœa, may be attained by the subcutaneous injection of strychnia ($\frac{1}{30}$ grain of the sulphate gradually increased to $\frac{1}{10}$, daily), or by systematic use of faradisation. The proper method of applying the current is by a laryngeal electrode, with a flat, spade-shaped extremity, that can be laid upon the pharyngeal mucous membrane, over the paralysed crico-arytænoid muscles. It is, however, very important that one should not be content with a partial success from this or any other plan of treatment. So long as the objective signs

of stenosis of the glottis continue, there is always the risk of the sudden supervention of a fatal attack of dyspnœa, as in a case recorded by Dr Semon in vols. xi and xii of the 'Clinical Society's Transactions,' in which the patient's life was just saved at the last moment by tracheotomy, and by artificial respiration continued for three and a half hours. The rule, therefore, seems to be that the trachea should be opened, as a measure of precaution, in every case of paralysis of the abductors, if attended with considerable stenosis of the glottis and with marked dyspnœa.

PARALYSIS OF THE ADDUCTORS OF THE CORDS.—There is, in every respect, the most marked contrast between paralytic affections of the abductors and of the adductors of the cords. They differ in their causes, in their symptoms, and in their course. Paralysis limited to the adductors is never due to organic lesions affecting either the fibres of the vagi or of the recurrent nerves, or their nuclei of origin; while it is not at all infrequent as the result of other causes, which seldom or never give rise to paralysis of the abductors.

The laryngoscopic appearances which accompany paralysis of the adductors vary somewhat according to the precise seat of the affection; for it is to be borne in mind that, instead of being (like the abductors) a single pair of muscles, the adductors consist of a group of muscles on each side of the larynx, any one of which may probably be paralysed separately. These muscles are classed together by Henle and Luschka under the name of the *sphincter sive constrictor rimæ glottidis*. Now, the pair of muscles which in this country are known as the thyro-arytænoidei are commonly supposed to have the function of relaxing the vocal cords, thus acting as antagonists of the crico-thyroidei. But the German anatomists divide the muscles in question into two on each side, the "thyro-arytænoidei externi," and the "thyro-arytænoidei interni." The thyro-arytænoidei interni are described as a pair of prism-shaped muscles, each of which has one of its edges projecting into the substance of the corresponding vocal cord. Their function is to straighten and approximate the cords in the act of vocalisation. In other words, they co-operate with, instead of being opponents of, the crico-thyroidei; and they are sometimes spoken of as the "internal tensors," the crico-thyroidei as the "external tensors" of the cords.

If, then, the thyro-arytænoidei interni are paralysed, the effect is that when the patient attempts to speak, the cords, instead of being straight, are both concave, and enclose between them a narrow oval space. If the affection is unilateral, the space appears bounded by a straight and a curved line. The width of the space between the cords depends partly upon the pitch of the sound which the patient is trying to utter, being greater when the pitch is low than when it is high. For we must remember that every degree of loss of power of the vocalising muscles may occur, from the slightest possible paresis up to the most complete paralysis.

Isolated paralysis of the arytænoideus muscle causes the rima *glottidis* to gape posteriorly, between the two arytænoid cartilages, while the cords themselves meet perfectly. The laryngoscopic appearance is then that of a triangle behind, with its apex prolonged into the normal narrow chink.

Another laryngoscopic appearance sometimes observed is that the processus vocalis of each arytænoid cartilage forms an angle inwards; it is believed to indicate a combination of paralysis of the thyro-arytænoidei interni with that of the arytænoideus.

Isolated paralysis of the two crico-arytænoidei laterales is said to produce in the laryngeal mirror a figure with an angle outwards corresponding with the processus vocalis on each side, the rima being quadrilateral and lozenge-shaped. Ziemssen, however, doubts whether such an affection of these muscles ever occurs.

If all the muscles forming the sphincter rimæ glottidis are paralysed at the same time, the rima glottidis, when the patient attempts to speak, forms an oval space; but this is not bounded behind by the point of contact between the two processus vocales, as when the thyro-arytenoidei interni alone are affected; it extends backwards between the arytænoid cartilages to beneath the posterior commissure.

Lastly, according to Mackenzie, it is possible to recognise by the laryngoscope a paralysis limited to the crico-thyroidei muscles, which differ from all the rest in receiving their supply from the superior laryngeal nerves. The appearance which indicates such an affection is said to be that the rima glottidis presents a wavy outline.

Paralytic affections of some of the muscles forming the sphincter rimæ glottidis may be associated with spasm of others; so as to make it impossible to determine the precise character of such cases.

The main symptom in all cases of paralysis of the adductors of the cord is impairment of voice, extending from hoarseness up to the most complete aphonia, so that the patient may be utterly unable to speak except in a whisper.* Paretic states of the various muscles give rise not only to hoarseness, but to an undue sense of fatigue in speaking or singing, and to inability to maintain the voice for long or to shout.

Functional Disorders of the Voice.—*Aphonia* is not only a symptom of paralysis of the adductor muscles from organic and permanent cause. It is also a functional and transitory condition. Probably in some of these cases there is no true paralysis, for many patients who have complete aphonia nevertheless continue to be able to cough, and also to sneeze; and these reflex acts are accompanied with a laryngeal sound, which clearly proves that for this performance the cords can be perfectly well brought into contact. This is especially apt to be the case with hysterical women, who, in fact, are the most frequent subjects of paralysis of the adductor muscles. Mackenzie says that he has met with such an affection in girls only eight or ten years old; but hysteria is by no means unknown at such an age. Phthisis is another disease in which paralytic aphasia is not infrequent. Mackenzie in 1865 examined at the Brompton Hospital thirty-seven consumptive patients in whom the voice was affected, and found that in eleven of them "the affection was purely functional." Sometimes paresis of the thyro-arytænoidei and transverse muscles follows an attack of laryngeal catarrh; it may then continue long after the mucous membrane ceases to show congestion. Mackenzie says that this frequently occurs in public speakers, especially in clergymen (*aphonia clericorum*). In other cases paralysis of the adductors of the vocal cords appears to be caused by the direct action of cold upon the affected nerve-twigs or muscles. Sometimes

* Whether such a total loss of voice is ever the result of the isolated affections of individual muscles seems to be doubtful. Ziemssen says that this effect can hardly be produced even by paralysis of the thyro-arytænoidei interni, so long as the crico-arytænoidei laterales and the arytænoideus remain in action, and bring together the processus vocales of the two arytænoid cartilages.

it is the result of over-exertion of the voice, as in singers; such cases are usually slight and transitory. But Mackenzie speaks of paralysis of the thyro-arytænoidei interni as being occasionally the result of an actual "sprain" of the muscular tissues in some undue effort at vocalisation, and as then proving exceedingly intractable. Paralysis of the transversus (or of some of the other muscles) seems to be sometimes dependent upon gummatous or other lesions directly destroying the substance of the muscle. Mackenzie also mentions poisoning by lead or by arsenic as a possible cause of paralysis limited to one or more laryngeal muscles; a case which he cites occurred in a painter, and is described as complete loss of power of the adductor of the right vocal cord.

It is a peculiarity of hysterical aphonia, which (as we have seen) is dependent upon paralysis of some or all of the adductors of the cords, that the patient is apt to regain the voice suddenly under the influence of violent emotion. The recovery in such cases may be either transitory or permanent. Since the introduction of the laryngoscope it has become the usual practice to treat such cases by the application of a powerful induced current to the interior of the larynx, and this leads to brilliant success. The method is as follows:—One electrode is connected with a metal plate fastened upon a necklet which is put round the patient's neck so that the metal plate rests on the front of the larynx. The other electrode consists of a small metal ball or sponge fixed to the end of a long curved stem, which can be passed down into the space between the vocal cords. The stem of this "laryngeal electrode" transmits no current until the end of it has entered the larynx; at that moment the operator with his finger presses down a key by which the circuit is completed. All observers seem to be agreed that the only way by which it is possible to count upon a successful result from this procedure is that of using on the very first occasion a current of great power, which is of course exquisitely painful, and makes the patient involuntarily utter a loud articulate cry; whereupon the electrode is instantly withdrawn. If less than this be attempted at first, Dr Semon finds that electricity often fails altogether. Mackenzie speaks of having cured cases of six, seven, eight, and even ten years' standing. Sometimes it is necessary to repeat the application of the induced current several times and during many weeks before a permanent result is attained. In some cases, however, the introduction of an electrode within the larynx is not required; it is sufficient to apply a current across the neck from one side to the other, the electrodes being placed one over each thyroid cartilage. Mackenzie has also occasionally succeeded with stimulating steam-inhalations of oil of Calamus aromaticus, or of creosote; or with a strong solution of nitrate of silver (ʒj ad ℥j) applied with a brush or as a spray.

Alteration of the pitch of the voice.—To complete the description of functional disorders of the voice certain cases must be mentioned in which there is an alteration in its pitch. Störk relates instances of children with an unduly low voice, and others of young men with an excessively high pitch, after their voice has broken at puberty. The remedy, in the former case, is to practise speaking with a falsetto voice; in the latter, with a bass voice. This is often perfectly successful, if sufficient perseverance be shown. Sometimes the desired change in the pitch of the voice is brought about very rapidly; for instance, a young man, aged eighteen, who for about a year had spoken in a falsetto voice which contrasted ridiculously with his

broad and well-built figure, was told to utter the vowel *u* for an hour daily in as deep a voice as possible, at the same time holding the head fixed, this last direction being merely for the purpose of keeping up his attention; on the fourth day his voice became normal, and from that time it remained so.

Spasms of the tensors of the vocal cords is another curious affection. This is characterised by a state of the voice so peculiar as to be at once recognised by those who are familiar with it. The following is Mackenzie's description:—"The patient is often able to produce some notes, either in his own natural voice, or in a slightly muffled tone; but, while he is speaking in this way, the current of the voice seems to be partially interrupted, and the sound conveys the idea of an arrested action of the respiratory muscles. In fact, it is very much like the straining and rather suppressed voice of a person engaged in some act requiring the prolonged and steady action of the expiratory muscles (parturition or defæcation). The patients often complain that they cannot get their voice out. After speaking a word or two, or even several sentences, in this peculiar tone, the patient may again utter a few words in a comparatively healthy voice, and then may immediately relapse into the diagnostic intonation." Or there may be a complete absence of sound, the lips moving in the usual way for the utterance of words and phrases, which nevertheless are lost in silence. A clergyman is described as having been greatly distressed by the fact that while he kept on reading the service some of the words dropped soundless from him.

Mackenzie, in 1880, had seen only thirteen cases of this kind; eleven of them were in men, ten being clergymen, and the eleventh a barrister; two were in women, both of whom had had constantly to speak to deaf relatives. Doubtless, therefore, it is the result of over-use of the voice. The onset of the affection was sometimes gradual, sometimes sudden; in the latter case it was attributed by the patients themselves to "catching cold." No treatment was permanently successful in any instance.

LARYNGISMUS STRIDULUS.*—Obstruction of the glottis by spasm is present in many diseases and not in one only, and in this disease there is, or may be, spasm of many other muscles besides those of the larynx. Hence it is both less and more than spasm of the glottis. Laryngismus stridulus in its extreme forms exhibits an organised series of phenomena, comparable only with those of an epileptic fit. As we shall presently see, there have been doubts as to whether it is dependent on a primary disturbance of the central nervous system, or whether it is reflex and due to peripheral irritation. But however this may be, its proper place in the nosology is certainly among the neuroses, where it is placed in the last edition of the College of Physicians' 'Nomenclature of Diseases,' and the only reason for discussing it in this place is that clinically its symptoms have to be studied in relation with those of laryngeal diseases. The name of laryngismus stridulus was invented by Dr Mason Good, and has since been very generally adopted; that of "child-crowing" was proposed by Dr Gooch. At one time it was called "thymic asthma," under the idea that it was caused by enlargement of the thymus. This hypothesis was maintained by Kopp in 1830, but was disproved by Bednar in 1852, and by Friedleben in 1858.

* *Synonyms.*—Spasmus glottidis—Spasmodic croup—Child-crowing—Thymic asthma—Millar'sches Asthma.

Symptoms.—In its simplest form laryngismus stridulus consists of a disturbance of the natural rhythm of the respiration, such that the child (for the disease is one of childhood) first holds its breath and then makes a more or less noisy inspiration. This occurs again and again at varying intervals —perhaps especially on the first waking from sleep—but neither parents nor nurses may attach much importance to it, thinking it is merely a "catching in the breath." Gradually the paroxysms assume a more serious character, or they may have begun in a severe form. The child shows signs of great distress and alarm. Its neck and back become arched, its chest and abdomen rigid, its eyes turned upwards, and its limbs tonically contracted, the thumbs being bent inwards, the fingers extended, and the wrists flexed, while the legs are thrust out, the soles turned inwards, and the toes stretched wide apart. Its face, at first pale, may turn purple, or of a ghastly leaden colour. Sometimes the fæces and the urine are discharged involuntarily, sometimes there is a noisy expulsion of flatus. After a few seconds, or a minute or two at the longest, the spasm yields. In all probability, while it lasts, the glottis is completely closed. As it passes off a chink is formed, through which the air can slowly enter, making a loud crowing sound. This usually ends the seizure, but sometimes two or more paroxysms occur in rapid succession. According to Steffen in 'Ziemssen's Handbuch,' a few unrhythmical and noisy expirations, and one or more whistling or crowing inspirations, precede the stoppage of the breath which constitutes the central feature of the attack. After the paroxysm is over the child frets or cries for a little while, or falls asleep; or it may at once seem to be as well as ever, returning with as much zest as before to its toys, or to any game in which it may have been engaged.

Fatal event.—But it does not always happen that a seizure of laryngismus stridulus ends favourably. Sometimes, instead of relaxing, the spasm persists until life is extinct. There is then, of course, no crowing sound, and there may be nothing whatever to indicate the cause of a death for which the parents are utterly unprepared. Some years ago the author made an autopsy on the body of an infant aged sixteen months, which had died suddenly and had been brought to the hospital by its mother. Nothing was found to account for such an occurrence, but on inquiry next day it was found that the child had previously had attacks of "child-crowing." Steffen relates the case of an infant six months old, who was one night taking the breast when it was attacked with slight spasm of the glottis, after which it went on sucking. However, the attack returned more severely, and the child fell backwards. Within a quarter of an hour Steffen was at the spot. The child had been laid in its cot under the idea that it was sleeping. He found it livid and dead, without any signs of spasm of the limbs or of any other part than the larynx. Sometimes, however, death is preceded by tremulous twitchings of muscles, or by a more or less complete epileptiform convulsion, exactly as is the case in other forms of asphyxia.

As may well be supposed, after death from laryngismus stridulus the brain and its membranes are found gorged with blood, but there is no reason whatever for imagining that the congestion is antecedent to the paroxysms or concerned in producing them. When the disease has been of some standing the lungs may, according to Steffen, be found emphysematous; if this is really the case, in uncomplicated instances of an affection in which there is only inspiratory dyspnœa, it has an important bearing on the theory of emphysema in general.

Pathology.—It is clear that many other muscles besides those of the larynx are concerned in the production of attacks of laryngismus stridulus. The preliminary stoppage of breathing may be perhaps attributed to a mere inhibition of the respiratory centre, rather than to spasm. Steffen says that with few exceptions the diaphragm and the chest walls are "in the inspiratory positions" when the pause occurs, but he can hardly mean that they are in the position which they normally occupy when inspiration is completed; for if so, how is the prolonged inspiratory movement that immediately follows to be satisfactorily accounted for? Even as to the part played by the intrinsic muscles of the larynx at the time when the crowing inspiration takes place there has been some difference of opinion. Some writers have doubted whether there is only (as is generally supposed) a spasm of the sphincter of the glottis, and have thought that there must be also paralysis of the opposing crico-arytænoidei postici. Now, in experiments on rabbits it is found that if the superior laryngeal nerve on one side is divided, and its central end is then excited by a faradic current, the result is a strong bilateral adduction of the vocal cords. But if stimulation of the centres in the bulb thus normally tends to evoke adduction, the only question that remains is whether, when it occurs, the nerve-fibres to the abductors are left out of the reflex circle, or whether these muscles are overpowered by their antagonists. The preponderant action of the sphincter seems best explained by the latter hypothesis, supported as it is by the facts already mentioned with regard to the relative liability of the two groups of muscles to paralysis.

Ætiology.—The most obvious fact in the ætiology of laryngismus stridulus is its relation to *rickets*. According to Steffen, at least nine tenths of all cases occur in rachitic children. By Elsässer it was thought that craniotabes was in a special way associated with the development of laryngismus, but this appears not to be the case. It is doubtless in consequence of their having all in turn been sufferers from rickets that laryngismus has been sometimes noticed in several children of the same parents. Dr Reid mentions a family of thirteen, of whom only one escaped laryngismus and four died of it. Children affected with laryngismus are not infrequently fat, so that their parents fondly imagine them to be hearty and strong; but this is quite compatible with their being highly rachitic. The relation of laryngismus to other rachitic spasmodic neuroses, tetany and carpo-pedal contractions, has been already noticed (p. 711).

A curious point, noticed by Henoch, is that laryngismus stridulus is of far more common occurrence in the early part of the year than later on. Dr Gee, among sixty-three cases, observed no fewer than fifty-five between the months of February and June inclusive. His explanation is that the extent to which children are kept indoors during the winter increases the irritability of their nervous centres.

The *age* at which laryngismus stridulus begins is generally from four months to two years. But Dr Reid relates cases in infants only a few hours after birth; and others occur in children of various ages up to nine years.

There is, however, one remarkable fact which shows that rickets can only be looked upon as a predisposing cause of laryngismus, namely, that the latter affection is much more frequent in boys than in girls. Steffen cites figures from different observers, showing that the proportion of males to females is higher than that of two to one. In relation to it he alludes to the circumstance that membranous croup also is far more commonly seen

in male children than in female; and this is still more markedly the case with false croup. Such an indication of a relationship between laryngismus and other diseases of the main air-passages no doubt tends to make one hesitate in assigning a principal place in its pathogenesis to an over-excitability of nerve-centres in the bulb.

What, however, are the facts as regards the occurrence of tetany and carpo-pedal contractions in children of the two sexes? On reference to some of the recently recorded cases of tetany it appears that the patients have been chiefly boys. And although chorea is well known to be more common in girls than in boys, one must remember that its seat is probably not in the bulb, but in the large basal ganglia; and, moreover, that it occurs at a later age, when the course of development may probably have altered the relations between the two sexes as regards the susceptibility of the nervous centres. In this connection it is perhaps worth noting that many more males than females, whether children or adults, succumb to tubercular meningitis.

Whatever may be the real bearing of these facts upon the ætiology of laryngismus, we may without hesitation reject another hypothesis which a few years ago had many supporters, namely, that it is always of reflex origin and dependent upon some irritation conveyed upwards to the nervous centres from the periphery. This was declared by Dr Marshall Hall to be the "only true mode of viewing" the disease, and he maintained that the cause of it was almost always to be found in a morbid state of the teeth, in disorder of the stomach, or of the bowels. A few years earlier, Dr Hugh Ley had endeavoured to prove that laryngismus was the result of mechanical irritation of the vagi nerves by enlarged bronchial or cervical glands. He did in fact show that glandular enlargement was often present. But it certainly may be absent; and no morbid anatomist who has learnt how frequently in autopsies upon children the vagi nerves are found surrounded by caseating glands, will assign to them any important share in its ætiology. When the nervous centres are in a morbid state, with gradually increasing irritability of their cells, explosions may be directly brought about by stimuli conveyed from internal organs, just as in severe cases they can be excited by merely touching the surface of a child's body. The analogy of epilepsy and of many other neuroses is quite in favour of this hypothesis. Still, the fact that what must be a constant stimulation produces intermittent effects shows how preponderant is the paroxysmal state of the nervous centres.

Diagnosis.—There is no other affection with which laryngismus stridulus can be easily confounded by those who know its symptoms. At the moment of an attack, if there had been none previously, or if the child's history were unknown, one might suppose the obstruction of the larynx to be due to a foreign body. It would be quite right to pass one's finger to the back of the throat to settle the question; but the subsidence of the spasm would show the real nature of the disease.

Prognosis.—The natural course of laryngismus stridulus, when undisturbed by treatment, varies greatly in different cases. Sometimes the attacks continue to be slight, and occur at wide intervals; sometimes they increase in severity and in number, until there may be thirty or forty in the twenty-four hours. In either case they may after a few weeks gradually become less frequent, until at length they cease entirely. Some writers have said that one case in every three proves fatal; but if mild and severe cases be reckoned together the prognosis is much more favourable. It is worse when

the child is very young; and according to Steffen it is better in girls than in boys.

Treatment.—The treatment of laryngismus stridulus is, in the first place, that of rickets—sunlight, fresh air, good food, cod-liver oil. A change to the country or the sea-side is often quickly followed by the subsidence of the attacks. Dr Ringer strongly advocates sponging with cold water twice or thrice daily. Of drugs, the most trustworthy is bromide of sodium, of which from three to five grains may be given as a dose. Many find syrup of chloral hydrate (ɱx—xx) the most efficient medicine; it is readily taken by young children, and is perfectly safe.

It is right to look out for any condition of distant parts that may possibly be concerned in irritating the nervous centres. If the gums are hot and tense they should be lanced. If the bowels are loaded a few aperient or vermifuge doses should be given; but it will not often be found that great results are thus attained, either in diminishing the severity or in reducing the frequency of the seizures.

When a paroxysm is so prolonged as to require treatment cold water may be dashed over the face and head, the body being perhaps immersed in a warm bath; or a bottle containing ammonia may be held to the nostrils. The inhalation of chloroform is recommended by some writers. In severe cases the nurse should be taught beforehand how to act should the emergency arise. Even if life should have apparently become extinct it may sometimes be restored by artificial respiration, as was pointed out many years ago by Mr Johnson in the fifth volume of the 'Dublin Hosp. Reports.'

Inflammatory affections of the larynx.—Laryngitis differs widely in its seat, its symptoms, and its course. Some forms mainly affect the mucous membrane, whereas others start in the deeper structures of the larynx. Clinically superficial laryngitis presents two varieties: first, those attended with dyspnœa so severe that it threatens life—these are commonly known as cases of *croup;* secondly, cases in which the chief symptom is impairment of the voice—*acute* or *chronic* catarrh of the larynx.

CROUP.*—In 1765 Dr Francis Home, of Edinburgh, published a tract of sixty pages, an 'Inquiry into the Nature, Causes, and Cure of the Croup,' a disease which he declared to be entirely unrecognised by medical writers, although it was known to the common people of Scotland by several distinct names, of which "croup" is one. In each of the *post-mortem* examinations which he made he found the trachea lined by a more or less complete membranous layer. Thirty-six years later, in 1801, another Scotch physician, Dr John Cheyne, wrote on the same subject a work which has become classic; his views upon the pathology of croup were the same as those of Home. In the meantime the existence of the new disease had become matter of common knowledge in England as well as on the Continent. The relation of certain other affections of the throat to Home's disease were discussed by his successor, so that in Cheyne's work a controversy was begun, which even now is not finally settled.

The word Croup is of English origin, and applies to the peculiar sound of the breathing in this disorder. It is properly a clinical term, but has

* *Synonyms.*—Cynanche trachealis—Cynanche stridula—Angina suffocatoria—Morbus strangulatorius.—*Fr.* Angine couenneuse trachéale ou membraneuse; Le croup.—*Germ.* Häutige Bräune; Der Croup.

unfortunately been associated with the pathological condition of membranous laryngitis. We have to inquire: (i) whether the membranous "croup" of the Scottish writers is distinct from the disease which has since been called *diphtheria;* (ii) whether it is distinct from a milder affection of the air-passages, named *false or spurious croup, stridulous angina, stridulous laryngitis, spasmodic laryngitis,** or *inflammatory croup.*

(i) *Croup and diphtheria.*—The controversy in regard to this point was definitely begun by Bretonneau, of Tours. In his earlier 'Memoirs on Diphtheria,' 1821—1826, he made it his principal object to prove that that disease and croup are identical. This view was adopted by his pupil, Trousseau, by Guersent, Barthez, and almost all the other leading French physicians. In England it was for a long time repudiated, but latterly it has met with a much more favourable reception. The late Dr Hillier advocated it in 1862, and since then Dr Johnson, Dr Semple, Sir John Cormack, and many others.

In the first place, we must remember that both Home and Cheyne were perfectly acquainted with the fact that the disease which they described was liable to be confounded with one which affected the larynx secondarily, having its original seat in the fauces. Home, in quoting Dr Hare's graphic account of the "morbus strangulatorius" in Cornwall (which was epidemic diphtheria in its most typical form), says that that complaint "appears more nearly allied to the malignant sore-throat, although it sometimes attacked the trachea." And Cheyne begins his section on diagnosis by remarking that he had seen several children, whom he would have supposed to be suffering under the second stage of croup had he not discovered sloughs upon the tonsils and uvula.

One argument in favour of the identity of membranous croup with diphtheria adduced by Sir William Jenner is that mucous membranes do not pour out lymph upon their surface when inflamed by ordinary irritants as serous membranes do; so that an affection of the larynx attended with the formation of false membranes must be a specific inflammation. But, both for the fauces and the air-passages, it is certain that this rule is far from being absolute. In the 'Guy's Hospital Reports' for 1877 (p. 384) seven cases were recorded by the author, in which those parts presented appearances indistinguishable from diphtheria as the result of scalds of the throat by boiling water, which the children had sucked from the spout of a teapot or kettle; one case of a boy, who got a bean into his right bronchus, and whose larynx and trachea were coated with lymph; two cases (already referred to at p. 263) of children whose fauces were irritated, one by a piece of hot potato lodging in the throat, the other by a burning stick, and in whom the morbid action took the same form; one case of a man aged twenty-four who was admitted for a cut throat, and who died of a plastic inflammation of the larynx, trachea, and bronchial tubes; three cases in adults in which membranous laryngitis was secondary to cancer of the pharynx, tubercular ulceration of the vocal cords, and syphilitic disease, for which tracheotomy had been performed; and, lastly, two cases, both in adults, in which a similar affection was associated with acute or a chronic pneumonia—sixteen in all. Many of the patients, indeed, had had tracheotomy performed some days before death, and it might be plausibly argued that a badly cleaned tube, if it had before been used for a case of diphtheria, might

* By an unfortunate confusion some writers have designated as "spasmodic croup" the entirely different complaint "*laryngismus stridulus,*" described above.

have inoculated the parts with the specific disease. This, however, would not apply to some of the above cases, nor to one recorded by Mr Parker ('Clin. Trans.,' 1875) of a child who had scalded its throat with hot water, and from whose trachea false membranes were drawn up by means of a feather almost immediately after the operation. Moreover, both Rietz and Oertel found it easy to set up a plastic inflammation of the trachea in dogs and rabbits by dropping a few minims of Liquor Ammoniæ into it through an external wound. Oertel performed this experiment on seventeen animals, and succeeded in every instance in producing artificial "croup"—*i. e.* a traumatic membranous laryngitis.

It was long believed that the false membranes in croup and in diphtheria presented constant differences, microscopical and chemical; but we now know that in diphtheria itself they vary in their appearance, in the relation which they bear to subjacent parts, and even in their histological characters, according to the part of the mucous tract upon which they are developed. This fact overthrows all the histological distinctions between the two diseases.

Oertel believes the presence of micrococci to be essential to diphtheria, but in the false membranes which he set up artificially in animals by dropping Liquor Ammoniæ into the trachea, he found micrococci, though in small numbers, and only in the more superficial layers. It is not certain that the micrococci which are generally present in diphtheritic membranes possess the importance which Oertel attributes to them (*supra*, p. 261); but their non-occurrence in croup might still be distinctive of that disease. As a matter of fact, however, other observers have failed in cases of diphtheria to detect the micrococci in false membranes below the glottis.

Another distinction between diphtheria and croup, on which some observers have laid great stress, seems to be capable of ready explanation. It is the clinical fact that marked symptoms of depression—a dry, brown tongue, sordes on the lips, petechiæ on the skin, hæmorrhages upon the internal serous surfaces—are present in the former, but absent in the latter disease. In many cases of diphtheria, however, no such symptoms show themselves until several days have elapsed; and since croup destroys life rapidly by the mere effects of the presence of false membranes in the air-passages, one could not expect it to be attended with signs of depression and of septicæmia, even if it is a modification of diphtheria.

Again, the fact that a definite exposure to cold has immediately preceded and apparently excited an attack of membranous laryngitis, seems to be no proof that the case is not one of diphtheria. At least Sir William Jenner says that he has seen cases which arose in this way, and which he believed to have been diphtheria, because albumen showed itself in the urine; and in the chapter on diphtheria (p. 262) Dr Yeat's observations are recorded (which seem to refer to faucial diphtheria occurring in adults) as to the frequency with which, during an epidemic, those persons were attacked who had immediately before been exposed to the night air. Was it diphtheria which (as Watson relates) seized Dr Gregory's twin children on the same night, after walking together in the evening during a cold wind?

On the whole, it appears manifest to the present writer that no criteria based either upon morbid anatomy or upon clinical symptoms avail to distinguish laryngeal diphtheria from croup; that is to say, that the case

in which diphtheria is limited to the air-passages are really undistinguishable from membranous laryngitis with symptoms of croup.*

Notwithstanding Dr Fagge's arguments in the 'Medico-Chir. Trans.' for 1879, and in the first edition of the present work, there is increasing agreement that the disease as we see it in London is one—faucial diphtheria or laryngeal diphtheria or both. Traumatic cases of membranous laryngitis may occur, and occasionally idiopathic cases of the same kind; but "croup" expresses a certain combination of symptoms, and though these may depend on membranous laryngitis, they may equally depend on acute laryngeal catarrh or spasm. In any case it is most undesirable to use "croup" as a pathological term.

(ii) *Croup and catarrhal laryngitis.*—The next question is, what relation to the croup of Home and Cheyne is borne by those cases of "croup"—not infrequent—in which the air-passages are certainly without false membranes? Bretonneau is supposed to have been the first who indicated clearly the points of difference, and his name for the cases in question was "stridulous angina." But the English writers of the end of the last century were well acquainted with the clinical history of non-membranous laryngitis, which was known to them as "spasmodic croup" or "spurious croup." Its peculiar characters are fully set forth in a paper which Mr Field, before the Medical Society of London, read in 1796.

The most distinctive features of this non-membranous croup are the suddenness of its onset and the alarming nature of the symptoms which it presents from the very commencement. A child who is apparently in perfect health, or who may have had a slight cold for a day or two, goes to bed without any sign of laryngeal affection, and falls asleep as quietly as usual. About eleven o'clock, or at midnight or a little later, he suddenly starts up in a state of extreme excitement and terror. He coughs incessantly, making a hard, hoarse, barking noise. He pants for breath, and each inspiration is attended with a loud crowing sound. His voice is hoarse and it may be very feeble, but it is not whispering as in "true (membranous) croup." His face, at first flushed, afterwards becomes pale and covered with a cold sweat. The parents are alarmed and the nearest

* Cases in which there is an affection of the fauces, such as would be commonly called diphtheria, are much less often traceable to contagion when the air-passages are affected than when they escape. There seems to be a regular descending scale of contagiousness, according as the morbid process falls with less intensity upon the tonsils and palate and with more intensity upon the larynx and trachea. Moreover, whereas diphtheria attacking the fauces is common in adults, nearly all the cases at Guy's Hospital in which these parts are but slightly affected, and the brunt of the disease has fallen upon the air-passages, have been in children below five years of age. Now, it is very improbable that such differences should exist, either as regards the contagiousness of the disease, or as regards its occurrence at a special period of life; but one sees at once that the recognition of these differences is exceedingly favourable towards the inclusion within the domain of diphtheria of cases in which the larynx and trachea are alone attacked, the tonsils and palate remaining free. For the latter cases are likewise peculiar to children, and their non-contagiousness is the very point on which the whole discussion turns.

Is it not preferable to adopt another solution of the difficulty which involves no such improbabilities? It is to assume that the greater number of the seven cases referred to at p. 882 were really not examples of diphtheria at all, although the fauces were affected. After all, it seems an absurdity to draw a fixed line at the edge of the epiglottis, and to say that so long as an inflammatory process is limited to the parts below it the case may be one of simple membranous croup, but that if it spreads above this line it must be due to the specific poison of diphtheria. No doubt the great difference in histological structure between the mucous membranes of the larynx and pharynx appears favourable to such a view. But we know that, whether in diphtheria or after a scald of the throat, no obstacle to the *descent* of an inflammatory process is offered by this difference in structure. Why then should it be a bar to the *ascent*, when the air-passages are first attacked?—C. H. F.

medical man is sent for in haste. But, instead of the child getting worse, each paroxysm of coughing is rather less severe than the preceding one; and after half an hour, or in two or three hours, he becomes calm and sleeps. In the morning, when he wakes up, his cough is still hoarse and barking, but it is not so hard; his respiration is attended with little or none of the whistling sound; his voice has nearly regained its natural tone. During the day the child is as cheerful as before and has but little cough; his pulse is not accelerated; he is scarcely, if at all, feverish. On the following evening the symptoms may return, though not often as severely as at first; and occasionally they may repeat themselves for several nights in succession with gradually diminished intensity.

It is doubtful whether attacks of this kind ever prove fatal. Trousseau speaks of having seen three cases in which death occurred. But the only one of which he gives details is that of a schoolboy, thirteen years old, who was suddenly seized with dyspnœa on walking in the morning, and who seems to have died at the end of about four hours. On *post-mortem* examination the laryngeal mucous membrane was found to be reddened and the arytæno-epiglottidean folds were a little swollen; the vocal cords were swollen, and on one of them "there was a slight membranous concretion, possessing, however, none of the characters of diphtheritic false membrane." Probably severe laryngitis would have developed if the patient had lived a little longer. It certainly was not a typical case of spurious croup as regards the hour at which the attack began, and the boy was much beyond the usual age.

At present, therefore, the pathology of spurious croup is a matter of inference only; but there can be little doubt that it depends upon catarrhal laryngitis, complicated with spasm of the glottis.

Another feature of this complaint is its tendency to recur again and again in the same individual. A child who has once had it is always likely to be attacked a second time if he is exposed to cold or wet; and up to the age of fourteen or fifteen every slight catarrhal affection is apt to be accompanied with the peculiar hard barking cough. When one hears that a person suffered from "croup" repeatedly during childhood, one may pretty safely conclude that the disease was "spurious," *i. e.* is not membranous laryngitis.

Cheyne, in the second edition of his work, discusses at considerable length the relation between the "Croup" of Home and this "spurious" or "spasmodic" affection, with the description of which he was familiar through the writings of Field and of Ferriar, a physician of Manchester, who had published an essay on the subject in 1810.* And he comes to the conclusion that there are no just grounds for admitting two kinds of croup. The affection in question "occurs," he says, "in those families which are subject to genuine croup; it arises from the same exciting causes (exposure to cold); it prevails during the same weather." He goes on to say that in many cases in which the breathing afterwards becomes permanently affected, the symptoms are for the first few days most marked during the early part of the night, the patient in the daytime seeming to have nothing the matter with him but a cough.

There are, however, two criteria which point very strongly to the

* After reading Ferriar's essay it seems to the writer probable that his cases of "true croup" would now be recognised as diphtheria, and that those of "spurious croup" would be called acute spasmodic laryngitis.

existence of "spurious" (catarrhal) as separate from "true (membranous) croup." One is the sudden onset of the complaint with all its symptoms in full force. The other is its liability to return again and again in the same patient. If spurious croup were merely an undeveloped or milder variety of membranous laryngitis, one would expect that those who are subject to it would be very apt, when the exciting cause happens to be powerfully in operation, to have it in its severe form. Yet it is a question whether a single instance has been recorded.

There can be no doubt that Cheyne included, in his description of croup, cases of "stridulous angina." Indeed, it would seem that every case which he details, as an example of spurious croup, recovered.

Trousseau says that although "stridulous laryngitis" (as he terms the affection) is very common, he had had only one case in his wards at the Hôtel Dieu, a principal reason for this being the sudden way in which it declares itself, and the rapidity with which it yields, so that children attacked by it are very seldom brought to hospitals. But in Guy's Hospital, between the years 1867 and 1876, there were admitted ten cases at least of croup (and probably several more) in which recovery took place, and in which there was no proof of the formation of false membranes. In many of these cases the symptoms were continuous for some days in succession; and the clinical reports very seldom say anything about previous attacks of a similar kind. Perhaps it may be that in London a form of non-membranous croup is of frequent occurrence which in Paris is not met with.*

* It is a striking fact that Dr George Johnson—who is anxious to draw a sharp line of distinction between the cases of membranous laryngitis (which he regards as examples of diphtheria) and those in which no such membranes are found (which he terms "infantile laryngitis" or "inflammatory croup")—is obliged to extend the definition of the latter affection beyond the narrow limits which had been set by the earlier English and by the French writers. In fact, in the last edition of Sir Thomas Watson's 'Lectures' (in which Dr Johnson's views are adopted) the whole description of "croup" is transferred bodily to the new "infantile laryngitis." This is no longer the harmless affection of Bretonneau and Trousseau, but a disease which "proves fatal sometimes within twenty-four hours and often within forty-eight hours," and which "may continue for five or six days before it terminates." Now, in the course of many years there appears to have been at Guy's Hospital only one case fatal, in which false membranes were not found after death. But, as already remarked, it often happens that there is no evidence of their presence during life.

It is an instructive fact that in two out of eleven cases of "idiopathic croup" which came under Dr West's care between 1839 and 1849, when diphtheria (at least in an epidemic form) was not prevailing in this country, there was "a scanty formation of false membrane upon the velum and tonsils." No doubt, in an individual case, the possibility that the disease may be diphtheria can never be absolutely negatived. The most important points against it would be the absence of a history of contagion, the circumstance that no other person in the house or in the neighbourhood had had anything that could possibly be set down as diphtheria, and (with due allowance for the facts stated at p. 262) there having been a direct exposure to weather or to some considerable change of temperature immediately before the commencement of the attack.

It must be admitted that belief of the frequent occurrence of true membranous croup in children, distinct from laryngeal diphtheria, is antagonistic not only to that of French and most modern English writers, but also to those of German pathologists on the subject. Even those who theoretically admit the existence of membranous laryngitis and tracheitis independent of diphtheria, in practice seem to assign to diphtheria almost all the cases that they see.

It is, however, an important question whether this may not depend upon the fact that on the Continent non-specific membranous croup is really a much more rare disease than in England. Cheyne makes the assertion that it is far less known in the temperate than in the northern regions of Europe; but one can hardly tell on what facts such a statement is based. Even in Great Britain the disease appears to be irregular in its distribution. Home states that in his time it was far more frequent in Leith and Middleburgh, which are near to the seashore, than in Edinburgh, and in that city Dr Alison found it most prevalent in those parts

Symptoms.—"Croup" as distinct from diphtheria and dependent on acute laryngeal catarrh with spasm, commonly begins with but slight severity. The child is noticed to be feverish, refusing its food, but asking frequently for water. Its voice is hoarse; it sneezes frequently; it may have rather a shrill cough. It complains of no pain in swallowing. After some hours, or not until the lapse of four or five days, symptoms characteristic of the disease first begin. Their onset is generally gradual, but it may be sudden and may come on in the night.

Of all these symptoms the most important is dyspnœa. The breathing is not only hurried but noisy. Each inspiration is attended with a peculiar whistling sound, which may be audible at a considerable distance; and a similar sound, or one of a more snoring character, may accompany the expiration. On uncovering the child's chest, one sees that the structures above the sternum and the clavicles, and the lower intercostal spaces, are all drawn inwards each time the child breathes. And as the disease advances, the epigastrium, the false ribs, and even the lower portion of the breast-bone itself, form part of a deep hollow, produced by the action of the diaphragm; this muscle being arched upwards into the chest by the atmospheric pressure, can only drag its attachments backwards towards the spinal column, where it contracts.

The cough, at first harsh and clanging, gradually grows husky and at length is inaudible. The voice, from being hoarse, becomes whispering, and is finally extinguished. When the child attempts to speak, its lips can be seen to move, but not the slightest sound is heard. The nostrils dilate with each effort to breathe. The head is thrown backwards as far as possible, and the spine is curved in the same direction. It is not very obvious why this peculiar attitude should be adopted, but the supposition is that the trachea is stretched, so that air can better pass by the side of the false membrane. Ferriar once saw the corpse of a child who had died of croup resting on its head and its heels, as if it had died of tetanus.

Besides its persistent difficulty of breathing, a child labouring under croup is also liable to frequent exacerbations. If lying or sitting in bed, the little patient starts up and throws itself into the arms of its mother or nurse; but the next instant begs to be put back into its crib. It clutches at anything within reach, or at its own throat, as if to tear away the obstacle to the free entrance of air. After a time it sinks back exhausted and may fall asleep. There is still a doubt whether such paroxysms depend upon muscular spasm, or upon the impaction of portions of false membrane or inspissated secretion in the chink of the glottis. Some observers think that the more constant dyspnœa is the mechanical result of a swollen

which are lowest in situation. Wet and marshy spots are said to be favourable to its occurrence. Some of the medical men practising in Norwich say that it is unknown in that city, which has a very dry and bracing air, although it is much exposed to cold easterly winds.—C. H. F.

An assailant of the position so ably defended by the author in the first edition of this work would need acquaintance with hospital and private practice, and with children's diseases in town and country, as well as in different climates, such as very few physicians possess. For a most valuable summary of facts and opinions on this important subject the reader is referred to the 'Report of a Committee appointed by the Royal Medical and Chirurgical Society,' ten years ago, "to investigate the relations of Membranous Croup and Diphtheria." There are numerous cases tabulated (64 by Dr Dickinson, 63 by Dr Gee, and 88 by Dr Fagge), and replies to a series of question put by the committee from a large number of physicians to London hospitals, as well as from others in the country and abroad (vol. lxii, 1879).

laryngeal mucous membrane, or of muco-purulent matter upon its surface, and refer the paroxysms to spasm of the laryngeal muscles.*

It seems likely that such extreme dyspnœa would be attended with albuminuria. But in the series of cases recorded by Mr Lamb in the 'Guy's Hospital Reports' for 1877, there was only one in which the symptom was detected, and here there were other grounds for believing the disease to be diphtheria.

Event.—When croup is to terminate favourably, the little patient's breathing becomes easier, its cough softer and more loose.

Remissions in the symptoms are not infrequent, especially in the morning hours. The child breathes better; his cough is less distressing; he partially regains his voice; he may ask for food, or get a little quiet sleep. But such a change sometimes ends in rapid exhaustion.

The approach of a fatal termination is usually indicated by symptoms of asphyxia. The cheeks and lips become pale and bluish; the forehead is covered with a clammy sweat; the child ceases to take notice, and lies with half-closed, drowsy eyes; the breathing becomes shallow; the pulse rapid and intermittent; and the extremities cold. Death is often preceded by convulsions.

Ætiology.—The chief exciting cause of croup is by all writers said to be exposure to cold. Dr Alison noticed that it was often produced by a child sleeping in a room newly washed, and consequently that in Edinburgh cases frequently occurred on Saturday night. Cheyne said that in all but three of the cases of croup which he saw there had been exposure to the weather.

It is stated that croup is more frequent in the winter than in the summer months, but this is doubtful. Perhaps, like acute pneumonia, it may attack those who are exposed to chill after a hot day, or during the cold weather which in our climate may occur at any season.

The *age* at which a child is most apt to be attacked with croup is between two and seven years. The complaint is rarely seen in infants at the breast; indeed, both Home and Cheyne thought that children weaned early were especially liable to it. In adults croup is unknown.

All writers agree in stating that boys are more often affected than girls, and this has been thought to distinguish cases of croup from diphtheria. Thus Sanné says that out of 1575 cases of "diphtheria" admitted into the wards of M. Barthez (where the number of beds for males and females is equal), 813 occurred in boys, 762 in girls. On the other hand, in 101 cases of "croup" occurring at Prague, Steiner found that seventy-seven occurred in males, twenty-four only in females. He defines croup as an inflammation of the air-passages attended with the formation of false membranes, and no doubt most of his cases were due to the contagion of diphtheria. The experience of a single institution like Guy's Hospital is too limited to afford a secure basis for a comparison of the numbers of the two sexes, but they show no considerable preponderance of males among the cases of diphtheria, while they do show it among cases regarded as non-membranous croup.†

* Niemeyer attributed them to paralysis of the same muscles, and says that after death their substance is found to be watery, pale, and soft. Of course, it is only during the act of inspiration that a whistling sound could be produced by paralysis; and, accordingly, he drew the distinction that when such a sound accompanies the expiration it is invariably caused by the presence of false membranes obstructing the glottis. This is very theoretical.

† This fact, taken with the difference in the frequency of the two forms at certain periods of the year, is undoubtedly an argument against the view which I have maintained as regards the connection between membranous and non-membranous croup.—C. H. F.

Diagnosis.—The principal points involved have already been mentioned in the discussion of the relations of croup to the "spurious" affection and to diphtheria. One must never forget that in reality none of the special symptoms do more than indicate the existence of laryngeal obstruction. The distinction between croup and other diseases of the larynx is based upon the acute character of the attack and upon the early age of the patient rather than upon anything in the symptoms themselves: but even children are liable to other affections attended with stridulous breathing.

A post-pharyngeal abscess, for example, sometimes gives rise to "croupy" dyspnœa and cough, although it is not obvious why this should be the case. One day when the author was visiting his patients at the Infirmary for Children the house surgeon reported that he had just been called to see a case of supposed croup, in which he had felt an abscess at the back of the fauces with his finger, and that relief was afforded as soon as the matter was let out. In a little child, eighteen months old, a patient of Dr Hudson, at Waltham Abbey, the respiration was rather of a snoring character than croupy, but there was a brassy cough. The abscess seemed to have commenced in a suppurative affection of the cervical glands, which had made its way inwards, instead of pointing externally. According to Steiner post-pharyngeal abscess occurs chiefly in infants at the breast, except when it depends on disease of the spine; it is more insidious in onset than croup.

Sir William Jenner speaks of abscess at the side of the larynx as another affection which may cause great distress in breathing by compressing the tube, and as not being always easy of recognition. The possible presence of a foreign body in the air-passages must never be forgotten. Laryngeal papillomata are too slow in their effects to be mistaken for croup.

The *prognosis* of croup depends on our definition of the word. That of membranous laryngitis or diphtheria is very grave indeed; that of acute catarrhal laryngitis with croupous symptoms is good, much better than for laryngismus stridulus in infants.

The *treatment* of "croup" also depends on our pathological diagnosis. That of "membranous croup" has been fully discussed in the chapter on diphtheria (p. 274).

Non-membranous croup or spasmodic laryngitis requires no active treatment; but it is usual to give an emetic of two to five grains of powdered ipecacuanha, with or without one sixth of a grain of tartarised antimony, repeated at intervals of ten minutes until free vomiting takes place. Jenner says that besides removing from the stomach any source of reflex irritation, and relaxing spasm by the nausea and faintness to which they give rise, these medicines also promote secretion from the laryngeal and bronchial mucous membrane, and so relieve the catarrh. He has observed that cases left to themselves last much longer, going on for two or three days, whereas, as soon as an emetic has acted, the child generally falls asleep at once. However, he follows it up with a dose of calomel and jalap. Another plan of treating croup is that recommended by Graves, of squeezing a sponge out of hot water—as hot as the hand can bear—and applying it beneath the chin, changing it as often as it gets cool, for ten or twenty minutes, until the skin becomes vividly reddened. One must always warn the relatives of a child who has had one attack of croup that it is likely to have others if it is exposed to cold or wet weather, and allowed to get chilled. Such children must therefore have special care taken of them, particularly as regards the warmth of their clothing; but they should be accustomed to

have the neck and chest sponged over every day with cold water, and Steiner suggests that they should gargle the throat with it several times a day. A child who has repeatedly suffered from this affection is sometimes left with a permanent hoarseness of voice.

Membranous laryngitis in the adult.—There is no question that diphtheria with membranous laryngitis is common to all ages, and that the disease to be next described, acute catarrhal laryngitis, is even more common in adults than in children. But whether or no children are liable to membranous inflammation of the larynx as an idiopathic sporadic disease apart from diphtheria, it is generally supposed that in adults the mucous lining of the larynx and trachea is incapable of producing a false membrane, except under the specific action of diphtheritic contagion. It is certain that fibrinous membranes are not produced in adults as they are in children, by traumatic inflammation—scalds of the throat, for instance; but, nevertheless, there are undoubted cases in proof that the adult larynx and trachea may become the seat of acute sporadic idiopathic inflammation, which leads, not to pus and catarrhal products, but to a fibrinous exudation and a false membrane.

The most conclusive one known to the writer is the following:—A pregnant woman was admitted under his care into Guy's Hospital, in December, 1879, with severe dyspnœa from laryngitis. She was taken ill with shivering, after exposure to cold, spat up membrane on the following day; and two days later a complete cast of the trachea with its bronchial ramifications was got rid of. She died after a week's illness, having previously miscarried; and there was found laryngitis, tracheitis, and bronchitis, with lobular bronchopneumonia and pleurisy. The pyrexia had been moderate; there was no hæmoptysis, no albuminuria, and, *post mortem*, all the other organs were sound. The fauces had been free throughout. Histologically the false membrane consisted of leucocytes and scanty fibres without blood-discs or epithelium ('Path. Trans.,' vol. xxxi, p. 30).

Laryngeal Catarrh with Aphonia.—From what has been said in the previous section it will be evident that this pathological term needs further clinical definition; for in cases of "spasmodic laryngitis" or "spurious croup" (or non-diphtheritic croup), catarrh of the larynx is probably present. But it is in clinical practice impossible to draw a broad line of distinction between cases of inflammation of the laryngeal mucous membrane attended with dangerous dyspnœa (whether from swelling or from spasm of the larynx, or both) and those of which the chief symptom is impairment of the voice. The latter are commonly known by the name of catarrhal laryngitis; and this, again, may be either acute or chronic.

1. *Acute aphonia* is a very common affection, but comparatively seldom comes under medical advice. Some persons are very subject to it; whenever they catch a cold they become hoarse or lose their voice, and this condition lasts for several days or even for weeks. It is particularly apt to occur in those who are intemperate and in those who habitually use the voice much, particularly in the open air; the reason being that in such persons the laryngeal mucous membrane is constantly more or less congested. It is common in those who are exposed to smoke and irritating gases, as firemen and workers in chemical factories. It may also arise as a complication of some acute disease, as enteric fever, but especially measles. The

chief symptom, beside the impairment of the voice, is expectoration of a little tough mucus, which comes away with a short hawking effort, hardly amounting to a cough. With the laryngoscope, according to Ziemssen, one may find that there is reddening and slight swelling of certain parts of the interior of the larynx, especially the hinder ends of the vocal cords, the interarytænoid space, or the false cords. During attempted phonation the cords may leave an oval space between them, exactly as though the internal tensors were paralysed. In somewhat more severe cases Störk speaks of the cords as looking red, dry, and lustreless, or even as being covered with yellowish-green crusts formed of dried-up exudation. They may also become ecchymosed, and sometimes their surface shows superficial excoriations.

The *prognosis* in acute catarrhal laryngitis is generally favourable. It must not be forgotten, however, that cases in which the early symptoms were those of mere catarrh sometimes run on into œdematous laryngitis; and, on the other hand, the affection, if neglected, may become chronic, and may then be exceedingly intractable.

In the *treatment* one of the most important points is that the patient should entirely abstain from using the voice. He should remain in a room of which the temperature is kept uniform. Steam inhalations should be frequently employed. Mackenzie advises the addition of tinct. benzoin. comp., or of succus conii (℥ij with gr. xx of sodæ carb. exsiccat.), or of lupulin (℥ss) to the hot water used for inhalation, the temperature of which should be from 140° to 160°. The patient should be encouraged to drink freely of demulcent liquids, such as barley water, linseed tea, and the decoction of cetraria or of althæa. Warm milk or *lac cum sevo* is a useful beverage. If there is great irritability of the larynx, evidenced by cough and tickling or pricking sensations in the throat, it should be kept in check by opium or morphia, or (according to Störk) by chloral or by lactucarium. A mustard-leaf applied over the larynx and trachea often gives immediate relief. Störk and others recommend, at the commencement of the disease, that a strong solution of nitrate of silver should be brushed over the cords, but Mackenzie thinks that this is better left undone.

The best way to overcome the liability to acute laryngeal catarrh, in those who are subject to frequent attacks of it, is to make the patient gradually accustom himself to daily sponging with cold water, and to exposing the throat in the open air without wraps, even in the winter. No one can avoid allowing a draught to play upon the neck from time to time indoors, or in a corridor, or in passing from house to carriage; and the more a person endeavours to keep the part protected the more surely will he suffer when the occasion arises. It is also important to live, especially during the night, in airy, cool, well-ventilated rooms. Warm, light clothing should be worn. A long stay by the sea-side in the autumn, or in the bracing air of Scotland or Switzerland, often does a great deal towards diminishing the susceptibility to catarrh in the following winter.

2. *Chronic laryngeal catarrh* often arises out of the acute affection, especially in persons who, in spite of hoarseness of voice, persist in attempting to continue duties requiring loud speech. Such cases are common in clergymen, schoolmasters, costermongers. Another frequent cause is extension downwards from a "granular pharyngitis." Störk believes that a liability to this form of chronic faucial irritation often passes by inheritance

from parent to child. He also thinks that it may be set up by a course of mercury or of iodine, or by inoculation of the nasal cavity with gonorrhœal or leucorrhœal discharge. As a rule, chronic catarrhal laryngitis occurs in middle life; it is more common in men than in women.

The principal *symptom* of this affection is hoarseness of voice, which may pass on to complete aphonia. The degree to which the voice is impaired may vary very much at different periods of the day. Mackenzie remarks that it is often greater when the patient first begins to talk after an interval of silence than it is a few minutes later, after he has gone on speaking for a time. The attempt to use the vocal cords often gives rise to a painful sense of fatigue, and there frequently are also complaints of a feeling of dryness or soreness in the throat, and of a tickling sensation leading to a constant desire to hawk or to cough. The expectoration is scanty, generally a viscid grey mucus, but sometimes yellow and puriform.

The laryngoscope shows all gradations of change, from a slight local injection and swelling of some part of the mucous membrane of the larynx, up to the most extensive and diffused redness of the whole interior of the organ. Mackenzie remarks that one vocal cord may be of a bright red colour while the other is white; he also says that the congestion may be limited to a small portion of one cord, this being always on the outer or attached side of it. Small pieces of mucus are often seen adhering to the mucous membrane at different points; in the form of whitish threads they may pass across from one cord to the other; in cases of long standing the whole surface of the larynx may be covered with secretion. During vocalisation the cords in many cases fail to meet one another. This may be due to swelling of the interarytænoid mucous membrane, which is sometimes so extensive as to form a convex projection even when the arytænoid cartilages are as far apart from one another as possible. But in addition to this a paretic state of the muscles is not seldom present. Ziemssen says that this is most frequently unilateral, in which case the opposite cord may pass across the middle line to meet the affected one.

Sometimes certain parts of the larynx are greatly thickened. Ziemssen says that this is especially apt to be the case with the epiglottis, the arytæno-epiglottidean folds, and the false cords. Lewin maintained that thickening of these folds is a particularly marked feature of "clergyman's sore-throat," but this is disputed by Mackenzie. Störk relates in detail a case in which the whole of the interior of the larynx was affected with an extreme degree of hypertrophy of its mucous membrane, so that there was great dyspnœa, rendering tracheotomy inevitable. The disease had been of fifteen years' duration. From the right false cord there grew a hard, solid, fibrous tumour, of the size of a hazel-nut; every part of the interior of the larynx was thrown into enormous folds and ridges. Polypoid excrescences are, indeed, not uncommon results of a chronic laryngeal catarrh. Another affection which has sometimes been observed under similar circumstances is a thickening of the mucous membrane below the glottis, reducing the channel for the passage of air to a narrow chink or ring; in almost every instance it has been necessary to open the trachea. Lastly, the vocal cords themselves sometimes become granular on the surface, a condition which has by Türck been designated "chorditis tuberosa" or "trachoma." It has been supposed to depend upon a partial dermoid change in the epithelium; but in one case Wedl found microscopically only connective tissue and nuclear overgrowth.

Enlargement of the mucous glands is not infrequent in chronic laryngeal catarrh. Mackenzie speaks of seeing their enlarged orifices upon the epiglottis and upon the posterior parts of the cords in some cases, either as pale specks on a congested surface, or as small red circles on a pale surface. Another morbid appearance, which Ziemssen regards as an accidental complication of catarrh, is a dilatation of the veins of the mucous membrane, especially upon the epiglottis or upon the cords.

There has been some difference of opinion among writers as to whether chronic catarrhal laryngitis is or is not apt to cause erosion or ulceration of the laryngeal mucous membrane. Störk says that such a result is not infrequent, and that when an ulcer forms over the *processus vocalis* it may give rise to expectoration of blood in sufficient quantity to suggest the presence of tubercular disease of the lungs.

This observer lays stress upon the occurrence of a vertical fissure in the interarytænoid mucous membrane. It is not peculiar to cases of chronic catarrh. Störk speaks of it as being extremely frequent, occurring in as many as 50 per cent. of those who attend his out-patient practice. The fissure, as the result of the traction upon its sides, assumes a rhombic form; so that the upper part of it, which is alone visible in the laryngeal mirror, appears triangular. Its detection is often very difficult; the patient must be placed in the position required for inspection of the trachea with the laryngeal mirror. The symptoms are not always very marked. Störk had seen a singer of reputation, whose voice remained perfect after such a fissure had existed for many years. Generally, however, there are symptoms which appear to be identical with those of chronic laryngeal catarrh. And sometimes the subjacent arytænoideus muscle becomes paralysed, in which case the patient's life may be made almost unendurable by the running down of fluid into the larynx whenever he attempts to swallow or even to lie down.

The course of chronic laryngeal catarrh is generally very tedious and protracted, one reason for this being the fact that patients will seldom carry out the necessary treatment with sufficient perseverance, imagining that they ought to be well in two or three weeks, and neglecting all precautions as soon as they begin to improve a little. There are, however, among schoolmasters and clergymen many who go to the opposite extreme, being so nervous and fidgety about their throats that they may almost be classed with hypochondriacs.

A good many cases recover perfectly under careful management. A very important point is that rest should be given to the voice, the patient either using a slate to express his wants, or at least speaking only in a whisper. He must also abstain from smoking, be very moderate in taking alcohol, and avoid all highly seasoned foods. Locally, if the larynx is irritable, the patient should make use of a spray containing bromide of potassium or carbonate of soda with a little morphia. But the chief therapeutic results are to be expected from the use of astringent sprays containing tannic acid (gr. j—v ad ℥j) or alum (gr. j—x ad ℥j), or from the systematic application of astringent solutions to the interior of the larynx by means of a brush. Mackenzie says that he generally employs a solution of chloride of zinc (gr. xv ad ℥j); he applies this daily during the first week, on alternate days during the second and third weeks, and afterwards less frequently. Ziemssen lays great stress on the value of the topical use of solid nitrate of silver fused upon the end of a

laryngeal probe; this he repeats at intervals of a week or a fortnight; it causes violent spasm, which, however, is at once relieved by filling the throat with cold water. When there is an interarytænoid mucous fissure, the application of solid caustic is the best treatment; this must, however, be done with great exactitude, for if the surrounding healthy mucous membrane is touched instead of the sore, the patient's sufferings will be aggravated instead of being relieved.

In many cases of chronic catarrh, electricity applied locally aids in restoring the voice; and some patients find benefit from a course of the waters at Aix-les-Bains or at Ems.

When great thickening of the squamous epithelium from long-standing laryngitis is present, the case becomes what Virchow described as *pachydermia laryngis*, in a paper read before the Medical Society of Berlin, July 27th, 1887. There is a flat diffused swelling of the membrane towards the back of the vocal cords.

TUBERCULOUS DISEASE OF THE LARYNX AND TRACHEA.—In the medical literature of the end of the last century is first mentioned a disease called *laryngeal phthisis*. This name is not a good one, because it suggests the idea that an affection of the larynx may give rise to wasting and to other symptoms like those of pulmonary phthisis, without there being any lesion of the lungs. That such is sometimes the case has, indeed, been asserted by Trousseau and by some other writers, and may appear to be clinically supported; but the experience of all pathologists is that when a tubercular affection of the larynx is found after death the lungs invariably contain tubercles also, and present other lesions of evidently long standing, even when there has been no evidence of disease during life. If laryngeal tubercle is seen in cases of acute general tuberculosis, old as well as recent disease of the lungs is always present; consequently, although it cannot be denied that tubercles might form in the larynx earlier than in any other part of the body, the pathological evidence points at present to the conclusion that primary tuberculous disease of the larynx does not exist.

Pathology.—The view that the laryngeal affection which accompanies pulmonary phthisis is dependent upon the formation of tubercles was originally advanced by Laennec. It was soon afterwards disputed by Louis, and since that time the fact has been repeatedly affirmed and as positively denied. There can be no doubt that one very seldom sees conspicuous grey or yellow tubercles in the larynx like those in the ileum. But the general belief of English pathologists has always been that the laryngeal affection is really tubercular, not merely because it occurs in a large proportion of cases of pulmonary phthisis, and often with tubercular ulceration of the intestine, but also because many laryngeal ulcers have thick and caseating edges. The question was practically settled by the careful investigations of Heinze, of Leipzig, who published a monograph on the disease in 1879. The basis of his work was a microscopical examination of the tissues in fifty cases of phthisis, in each of which there was disease of the larynx or trachea; for in many instances the morbid process involves not merely the upper but also the lower air-passages, sometimes as far as the bronchial tubes.

Heinze found that in forty among his fifty cases tubercles were plainly recognisable in the larynx; in thirty-nine of these forty there was ulceration, in one there was tubercular infiltration of the mucous mem-

brane without ulceration; in eleven of the forty there was likewise tubercular ulceration in the trachea: in eight the trachea contained ulcers which could not be shown to be tubercular. With regard to the remaining ten cases, in eight there were laryngeal ulcers not certainly tubercular, but in five of these the trachea showed tubercular ulcers, and in two there were no ulcers in the larynx, but tubercular ulcers in the trachea. In other words, there were only three out of the whole fifty cases in which tubercles were not detected either in the larynx or in the trachea, or in both. The tubercles were plainly visible to the naked eye in hardened sections. They lay partly in the mucous membrane, partly in the submucous tissue, but always on a plane superficial to the laryngeal mucous glands. They had often undergone more or less complete caseation. With regard to the non-tubercular ulcers of the larynx and trachea, Heinze states that there was nothing in their external appearance to distinguish them from those that were tubercular. In every instance, too, they were very superficial—in fact, little more than erosions, and they were generally confined to the vocal cords. It is, therefore, quite open to question whether they were not originally preceded by a formation of tubercles which had softened and been cast off by ulceration, as is believed by Virchow to be very frequently the case when a case of laryngeal phthisis fails to show a definitely tuberculous character. In the trachea, on the other hand, there seems to be no doubt that ulcers occur which are really non-tubercular; they appear as minute depressions of yellow colour surrounding the mouths of the tracheal glands.

In one point only Heinze goes too far; this is when he asserts that, from the exceedingly small size of laryngeal tubercles, those writers must be in error who in some exceptional instances have recognised tubercles in the larynx in making autopsies, or even by the laryngoscope during life. Türck, for example, figures a larynx from a dead subject, in which, besides tubercular ulcers, there was what he describes as miliary tuberculosis plainly visible to the naked eye. And tubercles, both grey and caseating, have several times been seen at Guy's Hospital in the laryngeal tissues. Considering how tubercles vary in size in other organs, those of the larynx may well be much larger in some instances than in others.

Koch's tubercle bacillus is sometimes found in the granulations of a laryngeal ulcer, but not abundantly; and great care must be taken that, if the secretion covering it contains them, they are not pulmonary in origin.

The fact that tuberculosis of the larynx never occurs independently of pulmonary phthisis, and that probably it never precedes the latter, naturally suggests that the upper air-passages become infected by the passage through them of tuberculous sputum. This notion was started by Louis, but he thought that the sputum acted merely as an irritant upon the parts with which it came into contact. At present one can form a far more definite conception of the way in which tubercle bacilli, settling upon the laryngeal or upon the tracheal mucous membrane, may germinate and invade the tissues.

Ziemssen maintains that a continuous tract of ulceration can sometimes be followed from a vomica in the upper lobe of one lung along the corresponding bronchial tube (which alone of all the bronchial tubes may be affected) through the trachea to the larynx.

Sex and age.—That tubercular disease of the larynx and trachea should be more frequent in men than in women might have been anticipated from

the fact that this is the case with pulmonary phthisis, but the preponderance of males over females is far greater; according to Heinze 33·6 per cent. of male phthisical patients have ulceration of the larynx, but only 21·6 per cent. of female phthisical patients.

The *age* at which tubercular laryngeal affections are absolutely most frequent is between twenty-one and thirty; but among fatal cases of phthisis the proportion in which the larynx is found diseased is relatively larger at a more advanced age, namely, between forty-one and fifty for males, between thirty-one and forty for females. During childhood tubercular disease of the larynx is not common; among nearly 400 cases Heinze found only nine in patients under the age of fourteen; in none of these was there ulceration of the trachea: one was an infant of eleven months.

Symptoms.—When the upper orifice of the larynx is affected, there is often extreme dysphagia, every attempt to swallow causing great pain and distress. The voice becomes hoarse and weak, and ultimately it is reduced to a whisper. In some cases, however, in which the true cords are entirely destroyed by ulceration, it is believed that the false cords may vibrate so as to produce harsh deep tones. The effort to speak is often painful. The cough becomes weak and hoarse and toneless.

Pain, cough, and aphonia are, however, common to other forms of common laryngitis, and it must not be supposed that marked symptoms of laryngitis occur in every case of phthisis in which the larynx is found after death to be affected with tubercular ulceration. A few isolated ulcers are often found when no laryngeal affection had been suspected during life; and experience in the deadhouse teaches that extensive superficial catarrh of the mucous membrane possesses far more constant clinical significance than does the presence of localised ulcers, however deep. On the other hand, there are many cases of phthisis attended with hoarseness or aphonia, in which no tubercle in the larynx can be detected, whether during life or in the dead body.*

Diagnosis.—In the laryngeal mirror what chiefly characterises cases of phthisis attended with impairment of voice, when there is no local tubercular disease, is the extremely *anæmic* state of the mucous membrane of the larynx.

Heinze lays great stress upon the recognition of *tubercular infiltration* of the mucous membranes, which (he says) is quite peculiar to this disease, and which was present in twenty-one of his forty cases. Its most frequent seats were the false cords and the arytæno-epiglottidean folds. He speaks of it as forming in the dead body a smooth tense swelling, of a greyish-white or greyish-yellow colour, often presenting on its surface the appearance of fine pale yellow granules, or spotted with points of hæmorrhage. Over the summits of the arytænoid cartilages tubercular infiltration gives rise to swellings which Heinze compares to two rounded sugar-loaves, and Mackenzie describes as "pyriform." The epiglottis, when it is affected,

* In 'Virchow's Archiv' for 1877, Fränkel, of Hamburg, endeavoured to find an explanation of such cases in the occurrence of lesions in the laryngeal muscles, the fibres of which he showed to have undergone a granular change ending in complete absorption of their substance and emptying of the sarcolemma, while at the same time the nuclei of the internal perimysium underwent increase. It does not appear that the patients who furnished the material for his observations had had any definite paralysis, and indeed the lesions which he detected were distributed equally over all the muscles. But paretic states of the thyro-arytænoideus internus are said to be not uncommonly present in phthisis, and Gerhardt has described paralysis of the right recurrent nerve as the result of its having become involved in thickened pleura covering the apex of the right lung.

appears rounded and thickened, or "turban-shaped." The false cords become greatly swollen, so that they lie in the same vertical plane with the true cords or even overhang them, while the entrances into the ventricles of Morgagni are greatly narrowed. Thickening of the interarytænoid mucous membrane gives rise to a local bulging or excrescence at the back of the glottis, to which Störk draws attention as characteristic of tubercular disease, it being all the more so because neither polypi nor other new growths are ever seen in that position. The cords themselves very rarely exhibit a true tubercular infiltration, but they may become swollen and rounded, a change which Heinze found to be dependent upon the presence of numbers of small round cells between their fibres.

In the trachea it is only in the posterior membranous part that tubercular infiltration occurs.

Tubercular *ulcers* have no distinguishing characters except their localisation, which is usually at the attachment of the vocal cords to the arytænoid cartilages. They are rarely either deep or hæmorrhagic.

Among Heinze's fifty cases, ulceration of the cords was present in no fewer than forty; on both sides in twenty-seven, on one or the other side separately in ten, at the anterior commissure in three; in eleven cases one or both of the cords were completely destroyed. In the laryngeal mirror an ulcer upon one of the cords may appear either as a narrow linear fissure, or as an excavation of its edge, situated upon a more or less reddened surface. When the process of ulceration is further advanced it often happens that the cord looks as if it were split up into two or three separate longitudinal bands, with very irregular edges, arranged one above the other like a short flight of steps.

The false cords are not so often ulcerated; of Heinze's cases only in fourteen, but in eight of these on both sides.

Over the arytænoid cartilages ulcers were present in twenty-three of Heinze's cases, sometimes towards the bases of the cartilages, sometimes upon their summits or towards the pharyngeal surface. Those which lie towards the bases of the cartilages are almost always bilateral. They are seldom, if ever, visible in the laryngeal mirror. They have a peculiar tendency to penetrate deeply into the tissues, so that they often reach the perichondrium and lead to necrosis of the cartilages. In the dead body their outline is seen to be irregular, their edges smooth or fringed with papillary outgrowths, their surface uneven and dirty grey.

The epiglottis was ulcerated in twenty-six of Heinze's cases, generally upon its laryngeal surface, sometimes upon its border, never on its lingual surface. Often there are great numbers of small round shallow ulcers; sometimes they run together into a large irregular excavation. The surface upon which they lie is often but little reddened. In some cases the substance of the epiglottis becomes eaten away from its margins inwards, so that it may present one or more deep fissures, with pointed processes between; or it may be reduced to a mere stump. In these cases the ulceration of course affects the lingual surface as well as the laryngeal. Indeed, the whole larynx may be found covered with ulcers varying in shape, in size, and in depth.

It must not be imagined that the detection of ulcers by means of the laryngeal mirror is always an easy matter, even when they come fully within the field of observation. Störk remarks that they are often recognised, not so much by the presence of an obvious depression in the mucous membrane,

as by a change in its colour and a deficiency in its natural lustre. Unskilled observers often take patches of puriform mucus for ulcers.

When the presence of ulceration of the larynx is established, it still remains to be considered whether it is tubercular. We have seen that in catarrhal inflammation ulcers are seldom found; so that the diagnosis generally lies between "laryngeal phthisis" and syphilis; the points of distinction will be discussed under the latter head (p. 900).

It must not, however, be supposed that, in the *post-mortem* room at any rate, ulceration of the larynx is of rare occurrence, apart from either tubercle or syphilis. In acute *pneumonia* ulcers over the arytænoid cartilages are not infrequent; and ulceration has been seen there, or upon the vocal cords, in two cases at Guy's Hospital in which there was double pleurisy with pericarditis, in two cases of erysipelas, in one case (probably pyæmic) in which there were abscesses both in the liver and in the brain, and in two cases of Bright's disease. One of these last-mentioned cases occurred in a man, aged twenty-four, who had been hoarse for three months before his death; all that was observed by the laryngoscope was that his cords were at one time reddened, but afterwards pale; at the autopsy a narrow linear ulcer extended over each cord for a quarter of its length. Heinze gives details as to eight cases in which ulcers were found in the larynx after death from various diseases.

Prognosis and treatment.—The author has met with three cases of phthisis in which the larynx after death presented what appeared to be the cicatrices of ulcers that had healed; and both Ziemssen and Heinze have recorded similar instances, some of which occurred in patients who had been repeatedly examined with the laryngoscope. One of Heinze's cases is that of a man whose right cord was much ulcerated; two or three years later this was found to have healed, and there were also cicatricial bands on the left cord, which must have become affected in the interval. Both this patient and another appeared to owe their recovery to residence in a southern climate.

At the meeting of the International Congress in London in 1881 Rossbach and some other observers spoke very positively with regard to the occasional "curability of laryngeal phthisis," while Krishaber virtually denied it. The former speaker attributed considerable value, at an early stage of the disease, to the inhalation of antiseptic agents; the latter declared that no such treatment was of the slightest use. Ziemssen lays stress upon the importance of giving absolute rest to the voice by maintaining perfect silence, or speaking only in a whisper, for months together. Mackenzie speaks of the local application of perchloride of iron, in strong solution, as sometimes greatly diminishing the irritability of the mucous membrane and so relieving the troublesome cough. Nothing, however, is so serviceable in this disease as the local *insufflation of morphia* as a powder, in a dose of $\frac{1}{8}$—$\frac{1}{2}$ a grain mixed with half a grain of starch. A special instrument called an "insufflator" is made for the purpose: it consists of a hollow vulcanite tube, one end of which is bent downwards so that it can be directed towards the orifice of the larynx; in the middle of the tube is a hole, through which the powder is introduced, and which is then closed by a moveable covering; the other end of the tube is connected with a piece of elastic tubing. In using this instrument the operator places the elastic tubing in his own mouth, and introduces the vulcanite tube into the mouth of the patient. He then blows the powder down into the

larynx, just at the moment when the patient is drawing his breath. Mackenzie says that as the greatest diminution of the sensitiveness of the affected parts occurs in rather less than an hour, it is well, when there is much pain in swallowing, to introduce the morphia at about that interval before the time of taking food. It may be repeated twice daily. If distress is caused by liquids entering the air-passages, all fluid nourishment should be thickened with arrowroot or corn-flour; and the patient is more likely to swallow well in taking off a good draught than in sipping. Sometimes it is necessary to administer food through an œsophageal tube for weeks together. Dr Wolfenden recommends the patient, in extreme cases, to drink only when lying in the prone position, or supporting himself on his hands and knees. *Cocaine* lozenges, taken before food, are of the utmost value in these cases, and proved so particularly in a severe one lately in Guy's Hospital, when all other means failed.* Tracheotomy is now and then required when there is extreme dyspnœa; but this operation seems in no way to retard the further progress of the laryngeal affection. In fact, all ordinary treatment of laryngeal phthisis must be regarded as only palliative. To this statement, however, exception ought perhaps to be made if severe and active cauterising agents are applied at an early stage. The actual cautery is sometimes used, but the application found most useful appears to be a 50 per cent. solution of lactic acid. This treatment was introduced by Dr Heryng, of Warsaw, and has been adopted by Krause and other specialists in Germany and England. Mr Symonds reports well of its results, especially if the lactic acid is applied after the tuberculous ulcer has been scraped with a curette.†

The duration of life in cases of tubercular disease of the larynx is seldom long. Mackenzie gives a list of 100 cases, of which seventy-nine ended fatally in from six months to two and a half years after "throat symptoms had become troublesome;" in nine only did death occur within six months; twelve were prolonged over a period of from thirty to forty-nine months. Ziemssen, however, maintains that the quickly fatal course of "laryngeal phthisis" depends rather upon the disease of the lungs developing itself rapidly than upon the affection of the larynx directly shortening the patient's life. According to this writer, when the pulmonary disease assumes a chronic form, laryngeal ulcers may exist for years.

LUPUS OF THE LARYNX.—Within the last few years a small number of cases have been recorded, in which lupus of the skin has been associated with a like disease of the epiglottis and the larynx. The affection is characterised by the presence of nodules, which may be as large as peas, and of ulcers, some of which have undergone partial cicatrisation. It is stated that the ulcerated epiglottis often looks as though a heart-shaped piece were taken out of the middle of its free edge. Otherwise there is nothing in the laryngoscopic appearances which could distinguish lupus of the larynx from the effects of syphilis; nor are there any peculiarities in the symptoms, which consist of hoarseness, sore-throat, dysphagia, and perhaps dyspnœa. Consequently the diagnosis of a case which Ziemssen gives as one of laryn-

* Mr Symonds remarks that a 10 per cent. solution of menthol in olive oil is a very soothing application, and more permanent in its effect than cocaine.

† Dr Clifford Beale has also written with judicious reservations, but decidedly in its favour, in an excellent paper on "Laryngeal Affections in Phthisical Persons" ('Birmingham Medical Review,' April, 1890).

geal lupus, in a girl of twelve, whose skin was free, depends chiefly upon the fact that treatment with iodide of potassium proved a failure. What is recommended for this disease is the systematic administration of cod-liver oil and energetic cauterisation with nitrate of silver. Scraping with a curette and the electric cautery have also been employed.

A remarkable case of fatal chronic laryngitis which was regarded by the writer as lupus occurred in a young man who was long under his care in Philip Ward in 1887. There was no lupus of the skin, and no signs or history of syphilis, but the epiglottis was seen to be ulcerated, and there was no appearance of tubercular ulceration of the cords, nor of phthisis. He was therefore put under iodide of potassium and mercurial inunction, but with no good result. Emaciation gradually came on, and he died after about a year's illness. Deglutition had been only possible for some time by the local use of cucaine, and the immediate cause of death was gangrenous pneumonia from particles of food gaining entrance to the air-passages. There was no proof of syphilis discovered after death, and only a trace of obsolete phthisis at the apex of one lung. The epiglottis was entirely destroyed; the cords were much less affected. The appearance of the larynx was quite unlike that of tubercular disease (museum, No. 1697[1]).

Mr Symonds reports only two cases from the Throat Department at Guy's Hospital. In both there was great thickening of the epiglottis, with but little destructive ulceration.

LARYNGEAL SYPHILIS.—Affections of the larynx resulting from syphilis are by no means rare, whether compared with other effects of the venereal poison or with other diseases of the larynx: their occurrence is to some extent determined by local irritation. They are frequent in persons whose throats are exposed to cold, and who abuse the voice, as, for example, in costermongers. And Mackenzie found that, contrary to what is believed to be the case with tubercular laryngitis, the larynx was far more apt to suffer from syphilis during the winter than during the summer. The commonest age is, as might be expected, between twenty and forty; but among those who suffer from laryngeal affections, as remote sequelæ of syphilis, it is not uncommon to find persons up to the age of fifty or sixty, or even seventy.

Some of the earlier laryngeal manifestations of acquired syphilis may occur within two or three months after infection; its more remote effects may appear five, ten, twenty, or even thirty years afterwards, when all other indications of the disease have long disappeared, and when the patient has almost forgotten it. However, perusal of some twenty cases that have at different times come under observation in the *post-mortem* room at Guy's Hospital leaves a decided impression that severe lesions of the larynx are much more often associated with cutaneous eruptions and other obvious signs of lues than are syphilitic affections of the viscera, as the brain or the liver.

In some cases, especially those of recent infection, the larynx shows nothing more than a superficial catarrh. In this there is nothing characteristic. Ziemssen warns his readers against supposing that a livid-red or dirty-brown injection of the mucous membrane justifies a diagnosis of syphilis. Nor does the protracted duration or obstinate recurrence of a laryngeal catarrh afford grounds for concluding that it is not simply inflam-

matory, although in the case of the pharynx such facts have sometimes a marked significance. Störk speaks of syphilitic catarrh of the larynx as so transitory that patients are seldom treated for it.

Next in order of development come *mucous patches*, or "flat condylomata" (p. 287). As to their frequency, widely different statements have been made. Some almost deny that they occur in the larynx; others say that they are often to be seen by the laryngoscope. Ziemssen says that their chief seats are the cords, the posterior laryngeal wall, and the false cords. They may also appear on either surface of the epiglottis. According to Mackenzie they differ from pharyngeal condylomata in being yellow rather than white, and in being generally accompanied by less marked congestion of the surrounding mucous membrane; he also says that they are less apt to undergo superficial ulceration, and that they generally disappear quickly, even without treatment.

At a later period of the disease *gummata* are of not infrequent occurrence in the laryngeal mucous membrane and submucous tissue. They are described as generally forming small rounded elevations, from the size of a pin's head to that of a small pea, of the same colour with the rest of the laryngeal surface, isolated or collected together into masses of considerable size. They may be seated upon the epiglottis, the posterior wall of the larynx, the false cords, or the surface below the glottis. In 1874 Mr Norton showed to the Pathological Society a gumma larger than a pigeon's egg, which occupied the right arytæno-epiglottidean fold, and reduced the air-passage to a mere chink, so that it caused suffocation. Laryngeal gummata often ulcerate, but sometimes they long remain stationary.

Cicatrices frequently form within the larynx, and produce an extraordinary amount of deformity. Sometimes a web is formed between the cords, as in several cases recorded by Elsberg, of New York. In other cases the epiglottis is dragged down and fixed to the side of the pharynx, or the parts forming the entrance of the larynx may be puckered together, so as to reduce it to a small round hole. Papillary outgrowths of considerable size are occasionally developed in the neighbourhood of syphilitic cicatrices, and increase the obstruction to the passage of air.

Syphilitic *ulcers* in the larynx are often observed. During the earlier stages of the disease they are generally superficial; afterwards they are apt to eat deeply into the tissues, and cause great destruction.

It has been much discussed whether syphilitic ulcers present any characters by which they can be distinguished. Türck maintained that some of these cases can be recognised at the first glance by their more or less circular form, by their excavated surface coated with a whitish-yellow material, by their edges, which are sharp, sometimes much raised, and surrounded by an inflammatory areola. A point of great importance is the comparatively rapid development of syphilitic ulcers. Störk remarks that a patient with extensive destruction of the epiglottis as the result of syphilis may still retain a fresh, healthy appearance, which is never the case where such disease is of tubercular origin. Tubercular ulcers are smaller than syphilitic, except when several have coalesced together; they are often numerous, affecting both sides of the larynx at once, whereas syphilitic ulcers are usually solitary; they are generally seated upon a surface which is pale and anæmic instead of being reddened. But ulcers of the larynx sometimes occur in persons who, having had syphilis, are also affected with phthisis; it may then be quite impossible to make a positive decision.

In some difficult cases great help is afforded by the presence of ulceration of the pharynx, or of the base of the tongue, which in tubercular disease of the larynx is very infrequent. Destructive ulceration of the larynx by syphilis is often preceded by a like affection of the fauces, which passes continuously from the pharynx to the epiglottis. At the seat of the earlier lesions cicatrices may often be observed to have already developed, and this is conclusive as to the syphilitic character of the affection, for in tubercular disease such partial cicatrisation is never seen.

A practical point in diagnosis is that while tubercular laryngitis makes the parts very sensitive, so that examination with the mirror is sometimes impossible without the local application of morphia in mucilage or of cocaine, the syphilitic larynx is, like the tertiary ulcer of the skin, singularly insensitive, so that such cases are the best for the beginner to practise on with the laryngoscope.

The *symptoms* of syphilitic disease of the larynx generally include hoarseness of voice, which may pass on to complete aphonia. Pain is often entirely absent; but if the epiglottis or some other structure at the entrance of the larynx is affected, swallowing may be exquisitely painful, although even in that case there may be an entire freedom from pain at all other times. It is wonderful how well some patients manage to swallow, even when they have lost a large part of the epiglottis; the base of the tongue is carried backwards, and keeps even fluid from passing into the interior of the larynx. Cough is often troublesome, and if there is extensive ulceration, muco-purulent exudation and blood may be expectorated in considerable quantity. In one case at Guy's Hospital hæmoptysis occurred to such an extent that the patient was thought to have phthisis; and Türck has recorded an instance of fatal hæmorrhage from an extensive ulcer of the left side of the interior of the larynx, exposing a necrosed piece of the cricoid cartilage. This is very rare in cases of tubercular ulcers of the larynx. Otherwise it is chiefly by the supervention of œdematous laryngitis, or perichondritis of the larger cartilages, that syphilitic disease of the larynx tends directly to destroy life. But Türck and Ziemssen believe that, in the case of the arytænoid cartilages, incurable necrosis is far less apt to follow deep ulceration when syphilitic than when it is tubercular. In some cases at Guy's Hospital a fatal termination has resulted from pneumonia, which was probably set up by the entrance of purulent matter from the affected parts into the bronchial tubes.

The *treatment* of syphilitic disease of the larynx should generally consist mainly in the administration of mercury, and inunction is perhaps to be preferred to other methods, as it is often important to produce an effect quickly. Spray inhalations with a weak solution of bichloride of mercury are said to be sometimes very serviceable. Sometimes it is advisable to brush over the affected parts with dilute tincture of iodine, or with a mixture of two parts of iodine, two of iodide of potassium, and ten of glycerine. When mercury has already been freely used, full doses of iodide of potassium should be prescribed internally. Tracheotomy is sometimes necessary, and cicatrices may have to be cut through with endolaryngeal instruments. Mechanical dilatation by means of tubes, without cutting, has been lately much employed, and with excellent results, as in a recent case of Mr Symonds', in a boy at Guy's Hospital.

Congenital syphilitic laryngitis is not uncommon, but is usually of only symptomatic importance, by causing aphonia. Cases, however, have occurred

of deep and severe ulceration leading to death. Two in brothers, aged between six and three, are recorded by Dr Semon in the 'Pathological Transactions' for 1880, and a third in a girl eleven months old by Dr Thomas Barlow, in the same volume.

Fränkel has recorded an instance in which a syphilitic infant, less than three months old, died from laryngeal stenosis, as the result of perichondritis with exfoliation of the cricoid and of the left arytænoid cartilages.

INFLAMMATION OF THE DEEPER LARYNGEAL STRUCTURES.—The inflammatory affections of the deeper laryngeal structures fall into two groups, those of the submucous tissue and those of the cartilages. The former may be described under the name of "Œdematous" or "Phlegmonous Laryngitis," the latter under that of "Laryngeal Perichondritis."

Œdematous or phlegmonous laryngitis.—This is the affection which is commonly but inaccurately termed *œdema glottidis*, the name having been originally given to it early in the present century by Bayle. The inaccuracy is twofold: on the one hand, the part diseased is not the *glottis*, or space bounded by the vocal cords, for (except in very rare instances) they remain free from swelling, which really affects the entrance of the larynx above; on the other hand, the morbid process is not a passive *œdema*, but inflammatory exudation of serum loaded with leucocytes into the submucous tissue, or diffuse purulent infiltration, or the formation of an abscess. Consequently there are some cases to which the designation œdematous laryngitis, others to which that of phlegmonous laryngitis, is more applicable. Perhaps a better name than either would be "submucous laryngitis," for the exudation is beneath the mucosa.

Œdema of the larynx in the sense of non-inflammatory dropsy is frequently seen in the bodies of those who have died of Bright's disease, or of heart disease, when the epiglottidean folds forming watery swellings are often of considerable size; such cases do not appear to present special symptoms during life, and probably have no clinical significance.

On the other hand, true œdematous laryngitis is one of the most rapidly fatal of diseases. The appearances, whether at the bedside or in the *post-mortem* room, vary somewhat with the exact locality of the inflammation. When the epiglottis is involved, it forms a turgid round mass, perhaps as large as the end of one's thumb, and often consists of two lateral rounded halves pressed closely together, so as to leave only a narrow gap between them. This may be either felt by the finger passed into the fauces or seen in the laryngeal mirror; occasionally it may be directly visible when the tongue is depressed with a spatula. Sometimes the tissues in front of the epiglottis are included in the swelling. In other cases the parts most affected are the epiglottidean folds, which may be converted into two large globular masses, tense and resisting, so that they feel like swollen tonsils. The mucous membrane covering the cornicula laryngis and that between the arytænoid cartilages may also share in the swelling, so that the movements of the cartilages are greatly impeded. Within the larynx the inflammation usually affects the false cords, which bulge downwards as well as inwards, so as to overhang and conceal the true cords. The latter are very seldom involved in the swelling, but Risch has recorded ('Berl. klin. Wochenschrift,' 1866) a case in which, having actually removed the larynx

within ten minutes of the patient's death, he found the true cords swollen to the breadth of half a centimetre and pressed against one another, so as completely to close the glottis. A similar instance occurred at Guy's Hospital in 1873; the patient was a woman who was found moaning on the ground in the street, and who died before she could be brought into the ward. In some cases the effusion is limited to the structures below the cords, constituting what Gibb termed a "subglottic œdema." Mackenzie speaks of such cases as generally chronic rather than acute; but Ziemssen cites five instances, one of them observed by himself, and all verified by the laryngoscope, in which the symptoms were urgent and rapidly developed.

The colour of the affected parts, as seen during life, is generally a bright red. After death they look much paler, the arytæno-epiglottidean folds in particular appearing gelatinous, and having often a yellowish-green colour from infiltration of pus into their tissue. When they are incised in the *post-mortem* room, however, it is often found that no fluid escapes from them, even under pressure. Sometimes the inflammation extends to the laryngeal muscles, which may be full of suppurating points.

Among the *symptoms* of œdematous laryngitis the most important is dyspnœa, which may increase with extraordinary rapidity until it destroys life by suffocation. Inspiration is commonly attended with a loud whistling sound. There is some pain in the throat, increased by speaking, and the larynx is tender when handled in the neck. The voice is not always much altered, but as a rule it becomes first hoarse and then extinct. The cough is hollow or sometimes toneless. If the voice, as is sometimes the case, becomes affected before the breathing, the explanation seems to be that the interarytænoid mucous membrane has been the first to become swollen. Another sign that this part is attacked is, according to Störk, an incessant dry jerking cough. If the epiglottis is inflamed at the beginning, there is intense pain in swallowing, and in all cases much distress is occasioned by the accumulation of buccal and pharyngeal secretions.

Störk lays great stress upon the significance of dysphagia as the earliest indication of commencing laryngitis in some cases, and upon the importance of using the laryngoscope whenever there is difficulty of swallowing, not obviously accounted for by an affection of the fauces. A thorough examination with the finger often at once clears up all doubt as to the nature of the disease. But this must be done with caution, lest it set up an attack of suffocative dyspnœa.

Ætiology.—Submucous laryngitis occurs chiefly in young adults between the ages of eighteen and thirty-five, and in men more often than in women. It is rarely seen in children.

As a primary affection, it appears to be generally due to some septic influence, such as is commonly but vaguely described as "blood-poisoning." Mackenzie says he has met with it in hospital physicians, in medical students, in nurses, as well as in persons exposed to emanations from bad drains. Sometimes it appears to be directly dependent upon exposure to cold, as in Trousseau's case of a man who, having drunk too freely at a wine-shop, was turned out into the street on a cold night, and fell asleep there, to wake with a violent sore-throat, which in an hour or two produced the most extreme dyspnœa. Sometimes it arises by direct extension from facial erysipelas, and sometimes it occurs in the course of smallpox, or of enteric fever. It is frequently the immediate cause of death in *angina Ludovici*, a diffuse inflammation of the connective tissue of the neck, with brawny

infiltration, which may or may not pass on to suppuration. In a case that occurred at Guy's Hospital in 1863 it was secondary to chronic suppuration in the fibrous tissues about the hyoid bone. It is often developed by extension from perichondritis of the laryngeal cartilages, or follows chronic tubercular laryngitis. Other frequent causes of submucous laryngitis are scalds of the throat, the entrance of a foreign body into the larynx, and the swallowing of mineral acids or other corrosive poisons.

Some writers describe it as being occasionally the immediate cause of death in cases of Bright's disease. Fauvel, indeed, maintained that it may be the earliest symptom of that disease. A recent case at Guy's Hospital in which acute inflammation of the submucous tissue of the larynx occurred as a secondary complication, was that of a man, aged twenty-seven, who died in 1878 of epileptiform convulsions. He had complained of sore-throat and of shortness of breath, but no symptoms had been observed indicative of laryngeal mischief. Both epiglottidean folds were found infiltrated with pus, but especially the left one. There was also much exudation of puriform lymph round the pharynx and at the base of the tongue. In the following year a man, aged thirty-four, who was lying in the hospital with cirrhosis of the liver, was attacked one day, at 11 a.m., with sore-throat, followed, at 4 p.m., by severe laryngeal symptoms, and by rapidly fatal dyspnœa at 10 p.m. After death the left epiglottidean fold was found moderately swollen with an effusion of serum, the right one smooth and shining, and greatly enlarged by infiltration with a semi-solid purulent substance. In a case of Bright's disease, which terminated fatally by dyspnœa in 1866, the autopsy showed that the cause was not ordinary œdematous laryngitis, but the exudation of a shreddy lymph-like material upon the mucous membrane of the larynx below the cords, extending down to about the eighth ring of the trachea.

Ziemssen relates the case of a young man who was attacked with extreme distress of breathing after eating some bread, and who ran off to the surgeon, thinking there must have been a needle in it, which was sticking in his throat. The laryngoscope showed that the right sinus pyriformis (outside the larynx) contained a pointed splinter of wood, which was at once removed with a pair of forceps. Only a quarter of an hour altogether had passed, yet there was considerable œdema of the right epiglottidean fold.

In cases of poisoning by corrosive liquids, laryngeal symptoms sometimes, after setting in suddenly and quickly reaching an alarming height, so that tracheotomy appears imminent, subside with no less rapidity.

In *treating* a case of œdematous laryngitis it is often well, at the commencement, to apply leeches to the neck over the sides of the larynx. Mackenzie recommends that bromide of potassium should be given freely, and that the patient should constantly suck ice. Trousseau speaks highly of spray inhalations impregnated with tannin or alum. If, however, the entrance of the larynx is found to be very greatly swollen, the best thing to do is to scarify the tissues thoroughly, so as to give the exudation an opportunity of escaping. A number of shallow parallel incisions should be made, the best instrument for the purpose being a "laryngeal lancet," or small double-edged knife mounted on a curved stem; but in an emergency an ordinary bistoury, covered up with adhesive plaster to within a quarter of an inch of its extremity, answers very well. If relief does not speedily follow tracheotomy must not be delayed. Above all, the patient must not be left,

even for a few minutes, until an opening into the trachea has been made, for a paroxysm of dyspnœa may set in at any moment, and may end fatally before there is time to fetch a surgeon.

Laryngeal perichondritis.—Several writers in the latter part of the eighteenth century recorded cases of suppurative laryngitis, with destruction of one or more of the laryngeal cartilages.

The usual opinion was that the disease began in the cartilages themselves, which (it was supposed) first became ossified and then necrosed. But it is generally admitted that the starting-point of such cases is in the perichondrium. Indeed, as far back as 1850, Dittrich, a very keen observer, pointed out, in an interesting article in the 'Prager Vierteljahrschrift,' that in a young subject it is not uncommon to find, when a small portion of the cricoid, happening to lie bare in an abscess cavity, is converted into a dirty yellow, calcified mass, that the rest of it and all the other laryngeal cartilages are in a perfectly normal state. The inference suggested by such observations is confirmed by a case at Guy's Hospital in 1859, in which the right ala of the thyroid and the right half of the cricoid were alike necrosed, whereas the left halves of their cartilages had escaped. Moreover, ossification of the affected cartilages is not always present, even in adult life. In a remarkable case of a child, eighteen months old, who died with "croupy" symptoms, we once found that part of the left half of the cricoid, which was bathed in pus, had undergone absorption, so that there was a gap in it, with thin smooth edges of perfectly natural appearance. And a year previously, in 1874, in the body of a man, aged thirty-three, the back part of the cricoid was necrosed, lying loose in an abscess cavity, while its anterior part was represented by a narrow edge of healthy cartilage, thinning off into fibrous tissue. Lastly, there is every reason to believe that disease of laryngeal cartilages is often not merely dependent upon an affection of the perichondrium, but secondary to ulceration which began in the mucous membrane. Probably this is the correct explanation of many of the cases in which such disease arises in the course of phthisis, enteric fever, smallpox, or syphilis. Dittrich suggested, in the paper already quoted, that in certain cases, occurring in persons confined to bed, necrosis of the cricoid is an indirect result of the pressure of this body, especially when ossified, against the vertebral column. His idea was that the pressure first caused ulceration and sloughing in the two opposed surfaces of the pharynx, and that then the affection of the anterior pharyngeal wall spread to the perichondrium. The morbid process would thus be strictly comparable with that which is concerned in the formation of ordinary bedsores; and Dittrich gave one case in which, the patient being a phthisical man, aged thirty-one, numerous bedsores were present at the time of death. He also recorded in detail two out of several cases in which, in bedridden patients, he had found that both surfaces of the pharynx showed local patches of ulceration, without the cricoid cartilage having as yet become involved in the disease. Störk satisfied himself that in severe enteric fever necrosis of the thyroid cartilage may arise in a similar way from pressure against the spinal column; and Ziemssen says that in old people, in whom the cricoid is ossified, that cartilage may be affected with perichondritis as a consequence of the repeated introduction of œsophageal bougies. Sometimes such disease is produced by direct injury, as in a case, recorded by Störk, of a man who was struck in the right side of the neck by a piece of

wood, which flew up while he was attending to a circular saw. In some cases, perhaps, it is the result of exposure to cold. In others no cause can be discovered.

Laryngeal perichondritis is much more common in males than in females. An analysis of twenty cases, collected from the pathological records at Berlin, showed that the period of life at which it most often occurred was between twenty and thirty years of age. But probably this was dependent upon the circumstance that eighteen of the twenty patients either were tuberculous or died of enteric fever. For at Guy's Hospital the disease, as a primary affection, has been more frequent in persons from thirty to fifty than in those who were younger. One patient was a girl under two years old, one a boy of nine, and one a man of sixty-three.

Hitherto we have spoken of perichondritis as though its necessary result were to produce suppuration and destructive changes in the subjacent cartilage. But there is every reason to believe that this is not always the case. It was remarked above (p. 871) that ankylosis of the crico-arytænoid joints may probably be caused by development of fibrous tissue as the result of perichondritis. Ziemssen records the case of a young man, in whom, during the course of enteric fever, a dark red flat projection appeared over one processus vocalis, causing hoarseness and severe pain. During convalescence this gradually diminished, and under favourable circumstances it might possibly have entirely subsided; but he insisted on going out, and after three days' exposure to weather and indulgence in alcohol, returned in a state of such severe distress that tracheotomy had to be performed.

When necrosis does occur, the cartilage is sometimes extruded from the abscess-cavity. An arytænoid is often expectorated entire; the larger cartilages commonly break up into fragments, which come away one by one. Störk speaks of having seen cases in which suppuration went on for years. When the necrosed material is completely got rid of, the cavity may be closed up by fibrous tissue.

The *symptoms* of laryngeal perichondritis vary with the exact seat of the affection. At first there is little to distinguish them from those of other subacute or chronic diseases of the larynx. The patient usually complains of hoarseness of voice or of aphonia; there may be dysphagia, cough, more or less definitely localised pain and tenderness; presently dyspnœa sets in, which may rapidly increase until it threatens suffocation. Sometimes the spontaneous evacuation of the contents of an abscess-cavity affords great relief to this symptom. In some cases of perichondritis enlargement of the cervical glands is a marked feature. In one case at Guy's Hospital they were found at the autopsy to be as large as plums. The putrid discharge which is formed in some cases is probably a direct cause of danger to the patient's life, by dropping into the air-passages and setting up pneumonia that may rapidly pass on into gangrene: two patients in Guy's Hospital died from this cause.

Perichondritis of the *thyroid* cartilage sometimes shows itself on the outer, sometimes on the inner surface of the cartilage. In the former case there is swelling, œdema, and at length fluctuation over one of the alæ or over the pomum Adami; the affected part is very tender when pressed upon. In the latter case a swelling usually appears in the position of one sinus pyriformis within the arytæno-epiglottidean fold on one side, or even below

the vocal cord, as in an instance recorded by Störk, in which it was mistaken for a polypus. Not infrequently both surfaces of the thyroid are affected in succession, so that when the abscesses have discharged themselves, milk or any coloured fluid can be injected through a sinus in the neck and run into the larynx, or a probe can be passed from without inwards until it is visible in the laryngeal mirror.

Perichondritis of the *cricoid* cartilage usually affects its posterior rather than its anterior wall. It causes marked dysphagia. Another effect to which it sometimes gives rise is paralysis of the crico-arytænoidei postici muscles, so that the cords appear fixed near the median line. In a case that occurred at Guy's Hospital in 1861 it is noted that the voice remained clear, although there was extreme dyspnœa. Sometimes the symptoms develop themselves with extreme rapidity. Ziemssen cites a case of Pitha's which ended fatally in a week from its commencement. Where suppuration occurs, the abscess may discharge itself into the pharynx, into the larynx, or into both canals at once. In some cases a swelling can be seen in the laryngeal mirror, bulging below one of the vocal cords; such a swelling has been mistaken for a solid new growth.

Perichondritis of an *arytænoid* cartilage leads to swelling and œdema of the surrounding soft parts, which may of course be visible in the laryngeal mirror. The mobility of the corresponding vocal cord is more or less interfered with, and the voice may be much impaired. Experience in the deadhouse impressed the author with the conviction that neither aphonia nor any marked alteration of the voice is nearly so constant a symptom of disease of an arytænoid cartilage as seems to be generally supposed. Cases of phthisis, in which complete exfoliation had occurred, had sometimes been free from laryngeal symptoms during life. In such cases there is a good deal of indurated fibrous tissue in the place of the cartilage, which seems to fix the cord and enable the muscles to act upon it sufficiently to maintain its functions. When an arytænoid has been exfoliated, an obvious falling in of the soft structures is often to be seen with the laryngoscope.

More than one of the laryngeal cartilages not infrequently suffer; one or both of the arytænoids, together with a part or the whole of the cricoid.

The *treatment* of perichondritis, if the disease is detected early enough, may sometimes be begun with leeches, the application of an ice-bag to the throat, and other antiphlogistic measures. When an abscess is recognised, whether outside or inside the larynx, it ought at once to be incised. Störk relates a case in which, having punctured a swelling below one of the cords and let out a quantity of pus, he subsequently brought the cavity to close by the systematic application of nitrate of silver to its interior.

In almost all cases, however, *tracheotomy* is required sooner or later; and when dyspnœa has once set in there is great risk in delaying it. The immediate result is almost always successful, but it rarely happens that the swelling of the laryngeal structures afterwards subsides enough to allow of the removal of the cannula. Schröter has had much success in the treatment of such cases by mechanical dilatation, at first with vulcanite tubes, and afterwards with pewter plugs, about an inch and a quarter in length, which can be left in the larynx for several hours at a time. Having been introduced through the mouth, the plug is held *in situ* by being bolted into the convex surface of the cannula which the patient is wearing.

LARYNGEAL TUMOURS.—New growths in the larynx are by no means very rare. From a clinical point of view it will be convenient to describe first benign, and afterwards malignant tumours.

With regard to the *causes* of benign growths in the larynx, almost the only fact hitherto ascertained is that they seem often to arise out of the irritation connected with chronic catarrh of the laryngeal mucous membrane. They are most frequently seen in persons who use the voice a great deal. They are far more common in males than in females, and, according to Causit, among children affected with laryngeal growths, boys are more numerous than girls.

Papilloma.—This, which is sometimes more accurately designated as *fibroma papillare*, is the commonest of all laryngeal tumours. It consists of a series of pointed or bulbous papillary excrescences, sometimes of small size, sometimes forming a large mass like a cauliflower, which may almost fill the cavity of the larynx. Their most frequent starting-point is from one or both of the cords, especially near their anterior extremities, or from the angle between the cords. But sometimes they arise from the false cords, or even from the epiglottis, seldom or never from the mucous membrane covering the arytænoid cartilages or the parts adjacent to them. Their colour may be either whitish, or pink, or red. They cause more or less alteration of voice, or even complete aphonia; cough, which may torment the patient greatly, and which may be of a "croupy" character; dyspnœa, which sometimes ends in actual suffocation. It now and then happens that the fragments of papillary growths become detached in the act of coughing, and are expectorated. Otherwise it is only with the aid of the laryngeal mirror that their presence can be accurately diagnosed. They not infrequently occur in young children. When removed by operation they are very apt to return, sometimes within a few months. Störk relates a case which came again and again under his observation during a period of thirteen years.

In cases of chronic laryngitis with papillary growths, Virchow finds that the lesion is usually situated towards the anterior ends of the cords. This *pachydermia verrucosa* is apt to be recurrent, but is not malignant. He looks on all the cases as simple, local, and only superficially hyperplastic, in which he finds a sharp line of distinction at the base of the epithelial growth separating it from the fibrous tissue beneath. Where, however, there is any trace of epithelium in the fibrous tissue, he considers the case suspicious. Neither the sessile nor the papillary swellings ought to show anything of an epithelial character below the border-line between the laryngeal epithelium and connective tissue. If there is no epithelium beneath this border-line, then, notwithstanding papillary outgrowths, he considers the disease to be local and benign.

Dr Percy Kidd has described a case of papillary tubercular tumours growing from the interarytænoid fold of mucous membrane in a man aged fifty, who died of phthisis with subsequent tubercular ulceration of the larynx and also of the colon. No giant-cells were discovered, but the other histological characters were those of tubercular growths, and characteristic bacilli were found abundantly ('Clin. Trans.,' 1884, vol. xvii, p. 156). Dr Kidd quotes only one other case of a young man from whose larynx several tubercular tumours were successfully removed by Schnitzler ('Wiener med. Presse,' April 8, 1883).

Fibroma, or fibrous polypus of the larynx.—This forms a round or pear-

shaped swelling, generally pedunculated but sometimes sessile, smooth or more or less lobulated, hard or more rarely soft in consistence, whitish or bright red in colour, varying in size up to that of a hazel-nut or even larger still. It is a solitary growth, its development is exceedingly slow, and it never recurs when it has once been removed by operation. Its most frequent starting-point is from one of the vocal cords, but sometimes it is attached to some other part of the larynx. Ziemssen figures one as large as a walnut, which arose from the mucous membrane covering the posterior surface of the cricoid cartilage. Growths of this kind most frequently occur in adult or middle-aged patients. Störk speaks of them as sometimes becoming ulcerated on the surface, so that they bled. In some few cases a fibrous polypus has become detached spontaneously and has been expectorated. With the laryngoscope the existence and the seat of this sort of tumour are generally easily recognised. Almost the only other possibility is eversion of the sacculus laryngis. Such a specimen, taken from the body of a man who had had no laryngeal symptoms, was shown to the Pathological Society in 1868 by Dr Moxon, and is now in the Museum of Guy's Hospital; it appeared like a semi-elliptical tumour hanging down in front of one of the cords, and could easily be replaced. Dr Lefferts, of New York, has diagnosed this affection in the living subject. The writer had a case in Mary Ward which presented this difficulty, but Mr Symonds found that it was not possible to push the projection into the tube of the larynx, as can be done when the mucous membrane is everted.

The symptoms produced by a fibroma of the larynx vary with its seat. Unless it is at a distance from the glottis the voice is almost always more or less affected, one reason for this being that even if the growth does not actually interfere with the apposition of the cords the surrounding mucous membrane is sure to be affected to a greater or less extent with catarrh. When a polypus has a pedicle of some length it may rise between the cords during phonation, and rest upon their upper surface, whereas during inspiration it falls down between them. The occurrence of dyspnœa is very uncertain. Dr Mackenzie had a patient who invariably slept with her hand resting under the neck, and who would immediately wake up with distress of breathing whenever by chance her hand slipped away. In a case recorded by Lieutaud about a century ago, the patient died of sudden suffocation as the result of stooping out of bed to pick up a book which had fallen on to the floor. He had been conscious some time of the presence in the larynx of something which he could not get rid of by coughing.

Mucous cyst.—This is sometimes found upon the epiglottis, as in a case which occurred in 1863 to Mr Durham, who has recorded it in vol. xlvii of the 'Med.-Chir. Trans.' The patient was a boy, aged eleven, who had suffered for some months from dysphagia, from hoarseness and feebleness of voice, and from attacks of dyspnœa which came on especially during sleep. The cyst, which was situated upon the laryngeal surface of the epiglottis, was incised, and gave exit to a glairy, thick, muco-purulent matter; it is therefore evident that the cyst was inflamed, and, indeed, the epiglottidean folds themselves were swollen and œdematous. In other cases a similar cyst has been found in the ventricle of Morgagni.

Dr Edis has recorded an instance in which there was a cyst of the size of a hazel-nut in the larynx of an infant, who died of suffocation thirty-seven hours after birth. Dr Abercrombie showed to the Pathological Society in 1881 a remarkable case of congenital cyst of the crico-thyroid

membrane, which blocked the glottis so much that the child (a female infant who died on the fourteenth day after birth) had never been able to cry or to breathe properly ('Path. Trans.,' xxxii, p. 33).

In some rare cases a laryngeal tumour has been a *myxoma*, a *lipoma*, an *angioma* (Mackenzie), or an outgrowth of the thyroid body penetrating the crico-thyroid membrane.

Treatment of benign tumours.—Mackenzie advises that small growths on the epiglottis or on the false cords should be left alone if they give rise to no inconvenience; he has observed several cases in which small "warts," after reaching a certain size, have ceased to grow.

Various instruments have been devised for the purpose of removing laryngeal tumours through the natural passages, or (as it is termed) by the "endo-laryngeal method"—knives (guarded or unguarded), cutting forceps, crushing forceps, guillotines, écraseurs, the galvano-cautery, have all found their advocates. It is needless to enter into details with regard to them, because it is not likely that any medical man would attempt to use them without having had special training, nor without consulting the works of those who have devoted themselves to the study of laryngeal affections. In choosing an instrument for a particular case, the degree of hardness of the growth and the character of its pedicle form important considerations; they must be determined as far as possible by the use of a laryngeal probe. It is not advisable to use an anæsthetic unless tracheotomy has previously been performed. The local use of cocaine in solution or as spray has, however, now superseded all other attempts to produce anæsthesia.

A point which must be remembered is that, *cæteris paribus*, more skill is required in the removal of a very small laryngeal growth than of one which is larger. Both in this country and abroad an extraordinary degree of skill has now been attained in the performance of endo-laryngeal operations. The immediate result of the introduction of laryngeal forceps, or of any other instrument, is the production of a violent spasm, with a feeling as of impending suffocation, but this quickly passes off. When there are a large number of papillomata in the larynx, repeated endo-laryngeal operations are of course necessary, which may run over a period of several weeks.

In cases in which it is difficult or impossible to operate through the natural passages, the question arises whether recourse should be had to "thyrotomy," or the division of the thyroid cartilage in the median line, with separation of its halves, enabling the surgeon to seize the growth or growths and to clear out the whole cavity of the larynx on a single occasion. This procedure, which had been adopted for the removal of foreign bodies nearly a century ago, was vigorously advocated by Mr Durham in a paper read before the Royal Medical and Chirurgical Society in 1871. But subsequent experience seems to have greatly limited the range of cases within which alone its performance can be justified. At the International Congress in 1881 opinions were almost unanimous with regard to this question. It was urged that the operation is attended with considerable danger to life from hæmorrhage, or from other consecutive evils, among which pneumonia and necrosis of cartilages with suppuration perhaps take the principal places. Further, it was shown that a permanent impairment or loss of voice is a not infrequent result of thyrotomy, though, on the other hand, there are many recorded cases in which the voice has been perfectly restored. Lastly, it was pointed out that in some patients there is great difficulty in getting the alæ of the thyroid cartilage wide enough apart to enable the operation to be

successfully completed, and that experience does not at all confirm the expectation that the risk of recurrence of multiple papillomata is diminished by the adoption of this procedure as contrasted with endo-laryngeal methods. Most of those who attended the Congress thought that even in young children (in whom multiple papillomata are so common) thyrotomy is seldom necessary. Krishaber related the case of a child, aged six, in whom he succeeded in rapidly removing a number of tumours without a laryngoscope by sliding a pair of forceps along his index finger into the larynx. One criticism it is fair to make upon the speeches delivered at the Congress; it is that laryngologists, not being so much accustomed to ordinary cutting operations, have probably in the performance of thyrotomy met with greater difficulties and obtained less satisfactory results than might occur to hospital surgeons in the like cases.

A mucous cyst in the larynx requires only to be incised and to have its interior rubbed with caustic. Contrary to what might have been expected, it seems seldom or never to fill again.

Malignant growths in the larynx are sometimes *Sarcomata*, generally of the spindle-cell kind. Ziemssen speaks of there being more than twenty recorded instances of such an affection; its seat is usually on or near one of the vocal cords. Mackenzie figures a sarcoma which he describes as growing from the posterior surface of the cricoid cartilage; it had a papillomatous character.

Carcinomata of the larynx usually belong to the keratoid variety, such as are commonly called epitheliomata. They must be rare in comparison with cancers of other parts, for in the *post-mortem* room of Guy's Hospital only some four examples have been met with between 1854 and 1883. All of them occurred in patients between the ages of fifty-eight and sixty-five. According to Ziemssen, however, they are not uncommon relatively to other laryngeal growths; he speaks of having collected 147 cases, of which thirteen had come under his own observation. Among the patients there were many more men than women. In one curious case the development of the disease was preceded, at an interval of some months, by a fracture of the thyroid cartilage, the result of an attempt at strangulation.

The larynx sometimes becomes affected with cancer by extension from the pharynx or from the base of the tongue. But in the cases now under consideration the starting-point of the affection is in the laryngeal mucous membrane, its original seat being generally one of the cords, one of the ventricles of Morgagni, or one of the false cords. In a case that occurred at Guy's Hospital in 1875, the amount of the growth at the time of the patient's death was remarkably small; the left arytæno-epiglottic fold showed a whitish thickening, with puckering, as of a healed ulcer, two or three lines in diameter; the thickening extended down to the false cord on that side: until the microscope revealed the structure of a carcinoma, it was doubtful whether a new growth was present. In another case, observed in 1862, there was a raised patch, somewhat papillary in character, growing from the left cord and the parts around. But in many instances, as the disease spreads, extensive ulceration occurs. The structures outside the larynx become infiltrated with the growth, which may protrude into the pharynx, or form an obvious tumour in the neck. The ulcerated surface within the larynx may pour out an abundant ichorous discharge mixed with blood, or may even be the seat of copious hæmorrhage. In such cases the breath

becomes horribly fœtid. Perichondritis, leading to suppuration and to necrosis of cartilages, often occurs as a complication. Death may be due to œdematous laryngitis, or (as in two out of four cases at Guy's Hospital) to pleuro-pneumonia and empyema.

The laryngoscopic diagnosis of carcinoma of the larynx is by no means always easy. At an early stage, when there is little beyond a diffuse infiltration of the mucous membrane, the case may be taken for one of perichondritis; and at a later period, when an ulcer has formed, it is often difficult to distinguish between syphilis and cancer, as in a remarkable case recorded by Ziemssen, in which he fortunately gave iodide of potassium with rapid and complete success, the patient being an old man of sixty-eight. Of the other symptoms *hoarseness*, seldom amounting to complete aphonia, is the most constant and generally the earliest. According to Ziemssen, indeed, it is almost the rule that there is a "prodromal hoarseness," lasting a year or two; and in several of the cases which he collected this was prolonged during three, four, or five years, and once even during twenty-six years. It is certainly difficult to suppose that the affection had a definitely malignant character throughout such long periods; and, indeed, Ziemssen's statements with regard to the duration of laryngeal cancer appear scarcely consistent with what one knows of the rate of progress of a similar affection of other parts: he speaks of several cases which lasted three or four years, and of some which lasted even six, ten, or fifteen years. Next to hoarseness, *pain*, which may either be seated in some one spot within the larynx, or referred deeply to the pharynx, is the most conspicuous symptom. And Ziemssen lays stress on the frequent radiation of pain into one or other ear; this pain in the ear he associates with the auricular branch of the vagus: he found it present in five out of thirteen cases in which inquiries were made about it, and sometimes when there was no pain in the larynx itself. As a rule, dyspnœa occurs sooner or later; it may be especially marked when the patient is lying down. There may also be dysphagia. In all cases of suspected carcinoma of the larynx careful search must of course be made for enlarged cervical glands; but Ziemssen says that they can seldom be detected within the first six months, and often not for a year, or even longer. However, in a case of Mr Durham's, in 1879, which was yet in an early stage, there were already two flat subcutaneous nodules, one near the right clavicle, the other on the edge of the left sterno-mastoid muscle. Secondary cancer of the viscera is very rare.

The *treatment* of carcinoma of the larynx can often be only palliative; but Ziemssen's case, already referred to, shows that whenever there can be a doubt as to the nature of the disease the patient should have the benefit of the chance afforded by a course of iodide of potassium. Indeed, at the London International Congress, in 1881, Dr Semon spoke of having seen this salt produce improvement in cases of cancer. Tracheotomy is generally required sooner or later; the average duration of life after this operation is said to be not more than a year.

It is chiefly in cases of malignant tumour that the question of the "total extirpation" of the larynx has to be considered. This operation, originally performed for syphilitic stenosis by Dr Watson, of Edinburgh, in 1866, was carried out in 1873 by Billroth with temporary success in a case of cancer. In a paper read in 1881 by Dr Foulis, of Glasgow, before the International Congress, reports of thirty-two cases are collected, in twenty-five of which the disease was carcinoma. In fourteen out of the twenty-five death occurred

within sixteen days after the operation; and in not one of the remainder was life known to have been prolonged more than nine months, the only patients who were stated to be alive when the paper was read being two who had been operated on three months previously. However, Bottini, of Turin, had one very successful case, in which the larynx was extirpated for sarcoma; in 1881, six years after the operation, the patient was well, and had been able to work in the fields and to act as a postman. This evidently suggests the possibility of a like success in cases of cancer, if they could be operated upon at a sufficiently early stage. Moreover, although the condition of those patients who have survived used to be very miserable, there being great difficulty in deglutition, in consequence of the large opening in the neck, which could not be closed, yet recent improvements in technique have greatly increased their comfort. The voice, moreover, can be more or less successfully restored by the use of an artificial vocal apparatus, such as was originally invented by Störk.

The results of about twenty partial removals of the larynx are on record, and of these nearly a fourth are reported as living twelve months after the operation. In more than 60 cases the larynx has been entirely removed; and of these a third died from the effects of the operation, 16 within a year from return of cancer, and 9 remained apparently cured sixteen months or more after the operation.*

In the case of the late Emperor Frederick, carcinoma of the larynx began as usual in a papilloma, and after its nature was recognised at a still early stage extirpation was advised. The fatal termination occurred about ten months later. In a more recent case of the same terrible disease, the affected half of the larynx was removed by Dr E. Hahn, of Berlin, and not only has life been prolonged till the present time, but the voice has been sufficiently preserved to enable the patient to continue his duties as the magistrate in a London police court.

MALFORMATIONS OF THE LARYNX.—This will be the most convenient place to mention certain congenital abnormalities of the larynx that occasionally give rise to clinical symptoms. One such appears to be almost confined to female infants, and causes the act of inspiration to be attended with a loud crowing noise, which is nearly constant, continuing even during sleep and after the administration of chloroform, though it is louder during the day. It is sometimes increased by exposure of the body to cold, or in other ways. The noisy state of the breathing is present from the time of birth, but disappears entirely at the end of about a year. Dr Lees has had an opportunity of making an autopsy in a case of this kind, in which death was due to diphtheria; and he found ('Path. Trans.,' 1883) that the epiglottis was folded on itself, like a leaf on its midrib, the arytæno-epiglottic folds being almost in contact. This condition had been seen in the laryngeal mirror during life, and it is probably not uncommon, for Dr Lees had seen three other cases, and it has also been recorded by Dr Gee and by Dr Barlow. It is important as simulating laryngismus stridulus.

Another and a much more serious malformation, described by Mackenzie, consists in a longitudinal bifurcation of the epiglottis, forming two flaps which (in a case that he saw) fell into the larynx, and caused constant symptoms of laryngismus from the first week and death at the end of four months.

* These numbers are taken from an abstract in the 'Brit. Med. Journ.' of June 16th, 1888, from Dr Max Scheier's paper in the 'Deutsche med. Wochenschr.' of June 7th.

Lastly, a congenital band of mucous membrane sometimes connects together the anterior parts of the cords. Mackenzie has recorded such an instance in vol. xxv of the 'Pathological Transactions.' The patient was a young lady, aged twenty-three, who had had complete aphonia from birth, never having cried, even as an infant. There seems to have been no dyspnœa. Laryngoscopically the web was seen as a flat membrane during inspiration, but on attempted vocalisation it became folded up, and protruded so as to resemble a tumour, of red colour, and of about the size of a haricot bean. It was excised, and the patient immediately afterwards spoke, and soon acquired a perfectly natural voice. In a case of Dr Poore's, exhibited at the International Congress in 1881, the patient, a girl of thirteen, could speak, but with a peculiar falsetto tone of voice; she had been liable to attacks of dyspnœa from infancy.

Foreign Bodies in the Larynx.—Not an uncommon cause of severe laryngeal symptoms is the entrance into the upper air-passages of foreign bodies of various kinds. As a rule, such bodies are sucked down into the larynx during a deep inspiration, as the result of coughing, laughing, sneezing, or talking while there is something in the mouth. In children the accident sometimes occurs during the night, in consequence of the habit of sucking a toy before going to sleep; and it may even happen to an adult who wears false teeth, unless he is always careful to take them out at bedtime. It is surprising what large things will sometimes enter the larynx. Mackenzie relates a case of a boy, aged six, who went to sleep with a toy engine in his mouth; during the night it was drawn into the air-passages, and tracheotomy had to be performed. The cause of the sudden attack of dyspnœa which had occurred was not discovered at the time, but some months later the toy was found impacted in the subglottic region, and was removed by thyrotomy.

The symptoms produced by the entrance of a foreign body into the larynx are generally at first very violent; there is a most distressing sense of suffocation, the face becomes cyanotic, the inspiration is prolonged and whistling, a cold sweat breaks out, the patient tears at his throat with the hands, under an irresistible impulse to relieve himself of the cause of his sufferings. Such a case may end fatally within a minute or two by asphyxia. But it is important to remember that if the air-passages are completely closed there is sometimes no obvious trouble with the breathing; the patient falls dead at once, and it may be only at the autopsy that the real cause is discovered of what had seemed to be an attack of syncope. In the act of vomiting, for example, it may happen that there is inhaled into the larynx a soft, pulpy mass, which entirely fills it.

In many cases a foreign body, having passed into the larynx, at once falls through into the trachea; the indications of laryngeal irritation soon subside, and are followed by a fresh set of symptoms, which will be discussed in the next section. In other cases, again, the foreign body is quickly coughed out into the mouth, after which it perhaps is swallowed, and ultimately passed through by the bowels. It may thus happen that laryngeal symptoms—brassy cough, dyspnœa, and alteration of voice—which were present for some little time, entirely disappear; and it is then difficult to decide whether there is still something in the air-passages or not. Another class of cases in which a diagnosis is not always easy occurs in hysterical women; such persons seek advice for tickling or pricking sensations

in the throat, which they declare to be due to the presence of a needle or a pin, or a bristle, but which are really "paræsthesiæ" of neurotic origin.

Finally, when a foreign body is of large size, or when it has pointed ends, it generally becomes fixed in the larynx, and may remain there, as in a case already alluded to, for a great length of time. At any period œdematous laryngitis may set in, attended with severe dyspnœa. But if the foreign body is impacted in the ventricle of Morgagni, there may be merely pain and cough, with perhaps some degree of hoarseness, but no dyspnœa. In such cases the diagnosis rests entirely upon repeated laryngoscopic examination.

When there is a foreign body in the larynx it has, of course, to be removed in one way or another, and generally by surgical interference. In most cases tracheotomy is required as a preliminary measure.

OBSTRUCTION OF THE TRACHEA.—The trachea and the main bronchi are liable to but few affections except such as are common either to the larynx above or to the tubes within the lungs below, and the clinical importance of such affections attaches itself always to the narrower rather than to the wider parts of the air-passages. Hence there is no need to give a separate account of tracheitis: the plastic form has been described under diphtheria; the tubercular with tubercular laryngitis, and the catarrhal form will be dealt with under bronchitis.

But there are a variety of diseases which at some point may narrow the calibre of the trachea or of the bronchi, with the result of producing a definite and characteristic group of symptoms. Of these diseases some have their seat outside the walls of the air-passages; others originally affect the walls of the air-passages themselves; and others, as in the case of foreign bodies, obstruct their channel from within.

Since it is often an accident whether in a given case the part narrowed is the lower end of the trachea or one or both of the bronchi, it is useless to attempt to separate the affections of these several parts from one another, particularly since both are often involved at the same time. All that is possible is to describe the special symptoms which in certain cases indicate that the obstruction is altogether limited to one of the bronchi, leaving the trachea free. The general designation, *obstruction of the trachea and bronchi*, includes the whole group.

A. Of the diseases which, starting *from outside*, may obstruct the air-passages and so cause what may be termed *stenosis* from *compression*, the following are the most important:

1. *Tumour of the thyroid.*—It is well known that a bronchocele may compress the trachea in the neck, flattening it from side to side, so as to make it "scabbard-shaped," and often pushing it out of the straight line or bending it. It is by no means the largest goitres which are most apt to have this effect; much depends upon the exact situation of the growth, and upon the condition of the overlying muscles, which oppose resistance to its extension outwards, but which were in one case found by Virchow to be in a state of fatty degeneration. Another point of great importance, for a knowledge of which we are also mainly indebted to this writer, is that the middle lobe of the thyroid, when it becomes enlarged, sometimes passes down behind the sternum so as to compress the trachea backwards against the spine. He even maintains that such a "substernal goitre" may be present without there being any obvious

swelling of the thyroid in the neck. This, however, seems to be doubtful. Ross, of Zürich, in a very able paper in vol. xxii of the 'Arch. f. klin. Chirurgie,' has drawn attention to a peculiar change in the tracheal cartilages which occurs as the result of the presence of a goitre, and renders them soft and flaccid. The way in which he recognises this after death is by dissecting off all other structures from the larynx and trachea and then placing them upright; the tube collapses at some one point, bending sharply so that its channel becomes completely closed. A like collapse is believed by him to be the cause of the supervention of sudden fatal dyspnœa as the result of goitre; he supposes that patients instinctively have to maintain the head in such a position as to avoid this occurrence, but that the muscles become relaxed during fainting, or sleep, or chloroform narcosis, or as the result of weakness. Dr Bristowe, for example, relates, in vol. iii of the 'St Thomas's Hospital Reports,' the case of a woman who was admitted for feverish symptoms, but who was one day suddenly attacked with intense difficulty of breathing, followed in a minute or two by blackness of face and insensibility. Fortunately he was close at hand, and finding that she had a tumour in the front of the neck, part of which was evidently cystic, he had this punctured, with the result that two or three ounces of a reddish-brown fluid were removed, and that she was quickly restored to health. In other cases enlargement of the thyroid is due not to a mere overgrowth of its tissues, but to the presence of a hydatid or of a malignant new growth, which may perforate the trachea and protrude into its channel; a well-marked instance of the latter event occurred at Guy's Hospital in 1873.

2. *Thoracic aneurysm.*—Among twenty-seven cases of aneurysm taken without selection from the *post-mortem* records of Guy's Hospital, there was interference with the trachea or with one of the main bronchi in every one. In fourteen the sac arose from the arch and pressed straight backwards upon the lower end of the trachea itself, flattening it, and often adhering closely to its walls. Probably in several of these cases the pressure extended also to one or both of the bronchi. But what is surprising is that in no fewer than seven cases the aneurysm seems (from the description given in the case-books) to have pressed solely upon the *left* bronchus: in three of these the sac arose from the summit of the arch on its left side, and pressed mainly upon the upper or upon the anterior surface of the tube; in the other four it came from the descending part of the arch and pressed forwards upon the posterior surface of the air-tube. On the other hand, there were only two cases in which the sac, having its origin in the right side of the arch, compressed only the *right* bronchus. The remaining four cases were examples of what is commonly termed aneurysm of the innominate artery; in them the sac pressed upon that part of the trachea which lies behind the upper part of the sternum or in the root of the neck.

It is difficult to say how many of the twenty-seven cases were characterised by other symptoms which actually did indicate, or might have indicated, the real nature of the disease during life. But in three instances the sac was of very moderate size. One, which flattened the trachea, was a round pouch "of the size of a walnut" (as seen at the autopsy), arising by a definite orifice from the posterior walls of an aorta severely affected with arteritis deformans. Another, which compressed and opened into the left bronchus, was "no bigger than a marble." The third,

which likewise interfered with the left bronchus, was "of the size of a small plum."

3. *Mediastinal tumour.*—In the period during which the twenty-seven cases of aneurysm were observed in the deadhouse at Guy's Hospital, there occurred nearly an equal number of cases in which the great air-passages were narrowed by mediastinal new growths; and among twenty-four of them in which details are given as to the exact seat of the lesion there appear to have been eight in which the obstruction affected the lower end of the trachea or both bronchi (sometimes much more on one side than on the other), six in which it was limited to the right bronchus, and ten in which it was limited to the left bronchus. In every instance the new growth invaded the walls of the air-passages, thickening them, and not merely pressing upon them from without. Indeed, there are two other cases besides those already mentioned, in each of which it is expressly reported that although the bronchus on one side was penetrated by the tumour, there was no narrowing of its calibre. Among the whole number of cases there seems to have been hardly one in which, if marked symptoms of stenosis were present, there were not also observed other symptoms and physical signs sufficient to show that the obstruction was due to disease beginning outside the air-passages. The pathological reports seem to justify the inference that mediastinal growths seldom invade the trachea or the bronchi at an early period in their development. It must, however, be remembered that they are not likely to be seen in the deadhouse at this stage, since, unlike aneurysms, they do not commonly destroy life suddenly and unexpectedly by hæmorrhage. In an interesting case of lymphosarcoma of the mediastinal glands, recorded by Weil in the 'Deutsches Archiv' for 1874, all the symptoms and signs of tracheal obstruction disappeared suddenly eight days before death; at the autopsy it was found that this was due to the giving way of the softened mass, which must have poured its substance into the air-passages, although the sputa had shown no fresh appearance even under the microscope.

4. *Mediastinal abscess.*—Abscesses of various origin may compress the trachea or a bronchus. A striking case is recorded by Schnitzler, in the 'Wiener Klinik' for 1877. The patient was four years old; an abscess as large as a child's fist pushed the trachea forwards and to the right; its starting-point was caries of the second and third dorsal vertebræ.

5. *Caseous disease of the bronchial glands.*—This is commonly given as one of the causes of obstruction of the trachea or of a bronchus, especially in children. Vogel, however, says that although there may be slight flattening or indentation it does not go on to actual stenosis. On the other hand, Widerhofer, in Gerhardt's 'Handbuch,' describes this occurrence, and also cites instances in which after prolonged dyspnœa abscesses dependent on disease of the bronchial glands discharged into the air-passages with relief to the urgent symptoms.

6. *Carcinoma of the œsophagus* is mentioned by Riegel and other writers as an occasional cause of stenosis of the trachea. But although it frequently invades the air-passages, it is rare for it to produce symptoms indicating interference with the entrance of air. As already remarked (p. 871), it may cause a bilateral paralysis of the abductors of the glottis, and so render the performance of tracheotomy necessary. In all probability the emaciation which is so marked a symptom of œsophageal cancer is attended with great diminution in respiration.

7. *A dilated left auricle*, secondary to mitral stenosis, may compress the left bronchus, as was first pointed out by Mr Wilkinson King in 1838, and as may be still seen by his preparations in the museum of Guy's Hospital. Friedreich has recorded an instance in which pressure on the bronchus from this cause was actually diagnosed by physical signs four years before the patient's death. At the autopsy, made by Virchow, it was found that only a very narrow channel was left.

B. Of the diseases which, starting *in the walls of the trachea* or of the main bronchi, may narrow the calibre of the air-passages, some are exceedingly rare. Demarquay, for example, is cited by Riegel as having observed a case in which such an affection arose from ulceration in a case of glanders. Langhans, in the fifty-third volume of 'Virchow's Archiv' (pl. xiii), recorded in 1871 an instance of primary carcinoma, having its origin in the mucous glands of the lower end of the trachea and right bronchus, which destroyed the life of the patient, a man of forty; it appeared as a warty affection of the lining membrane, extending also by infiltration into the muscular and fibrous external coats. Whether a simple local inflammatory process is capable of thickening the walls of the lower air-passages, so as to obstruct their calibre, is doubtful. Andral and Wilks are quoted by Riegel as having reported such cases; but the observations of Wilks refer to syphilitic stenosis only.

Syphilis is, indeed, by far the most important cause of obstruction of the lower air-passages, if the diseases producing compression from without be excluded. Gerhardt, in vol. ii of the 'Deutsches Archiv,' alluded to twenty-two examples of it of which he had made an analysis; and seven instances presented themselves in the *post-mortem* room of Guy's Hospital between 1861 and 1874. Sometimes the disease is limited to a single spot in the trachea, as in a specimen, taken from a patient of Dr Bright's, which is contained in the museum of Guy's Hospital, and in which opposite the second ring there is a contraction, as if produced by a ligature. Much more often it extends along the trachea; it may occupy its whole length, and may be prolonged into one or both of the bronchi.

The bronchi are seldom affected when the trachea escapes. But Wilks, in the 'Guy's Hospital Reports' for 1863, relates a case in which the right bronchus alone was stenosed; and in another case, observed at the hospital in 1875, the lesion was found to have attacked only the left bronchus and the upper branch of the right. Both bronchi were narrowed, with the trachea free, in a third case ('Path. Trans.,' vol. xxviii, p. 336). The mucous membrane is commonly raised into a series of irregular bands and ridges, which Wilks has taught us to regard as the cicatrices of former ulcers. Gerhardt, indeed, has reported a case in which at the time when death occurred from a form of chronic pneumonia there was simply an unhealthy ulcer with raised edges, occupying the right bronchus and one of its branches for about an inch, and exposing the bronchial cartilages. But the view taken by German pathologists generally is that the fundamental lesion is a diffused thickening of the whole tracheal wall, raising its lining membrane into folds and prominences. They describe ulceration, more or less extensive, as of not infrequent occurrence, but they regard this as secondary. It may spread deeply, setting up perichondritis, and leading to ossification and necrosis of the tracheal or bronchial cartilages, which may be exfoliated and appear in the sputa; or it may penetrate to the tissues outside the air-passages, and

form an external abscess. In a case that occurred at Guy's Hospital in 1865 there was perforation of the aorta, so that the patient died of sudden hæmorrhage. In other instances the tracheal rings, instead of being exposed and detached, become atrophied and bent on themselves or dragged one over the other. Whether syphilitic stenosis affecting a bronchus ever leads to its complete obliteration is doubtful. When such a condition has been found it has been regarded as congenital. Thus Ratjen, in vol. xxxviii of 'Virchow's Archiv,' described a case occurring in a man aged forty-nine, whose left bronchus was converted into a fibrous cord for an inch and a half of its length, the corresponding lung being quite airless, while the right lung was enormously enlarged, and apparently in a state of true hypertrophy, its air-cells being of normal size. But, as Cohnheim observes of this case, the presence of pigment in good quantity in the collapsed left lung is clear proof that it had at one time been functionally active.

With regard to the age at which syphilitic stenosis of the trachea proves fatal, it is worth noting that the large majority of cases at Guy's Hospital have been in persons between forty and fifty years old, and it has occurred in men far more often than in women. Among the cases collected by Gerhardt there was a far wider range of ages; one patient was under ten, and another under twenty: probably these are the two cases which he refers to inherited syphilis. Two instances of syphilitic stenosis in children twelve years old are given by Widerhofer.

c. Obstruction of the lower air-passages may be due to a *foreign body*. As already remarked (p. 915), a foreign body which enters the larynx through its upper orifice rarely remains fixed there, unless it is either very large or pointed in shape. Beans, peas, nut-shells, pebbles, small coins, fragments of bone, often fall into the trachea. Sometimes they remain free for a time, moving up and down as the patient coughs. One may then be able to feel the impact of the foreign body against the side of the trachea with the fingers placed outside the patient's neck, as was observed by Mr Lucas in the case of a child with a pebble in its air-passages ('Clin. Soc. Trans.,' xv). Even in that case there were physical signs which rendered it probable that the pebble lay in the right bronchus in the intervals between the fits of coughing.

As a rule, such bodies soon become fixed in the right bronchus or in one of its main divisions; the reason why they enter it rather than the left bronchus being that the fork between the two is slightly to the left of the middle line, so that the opening into the right bronchus is rather the more direct. Sometimes, however, the left bronchus is the one into which a foreign body passes; and sometimes each bronchus in turn, the body becoming dislodged by cough, and falling now into one, now into the other. In certain cases the cause of obstruction is not, strictly speaking, a foreign body at all; it may be a tooth or a fragment of uvula, or a pharyngeal polypus separated by the hand of the surgeon; it may even have found its way into the air-passages by ulceration from the living tissues, as when it is a necrosed laryngeal cartilage, a concretion from a bronchial gland, or a hydatid from the liver. An accident which has several times happened after tracheotomy is that a portion of the tube has become detached from the rest and has dropped into the trachea. Altogether the literature of foreign bodies in the air-passages is very extensive, no fewer than 374 recorded cases having been collected and analysed by Kühn.

As may be supposed, foreign bodies are most frequently found in the air-passages of children and of lunatics. But other patients also, when attacked by sudden and violent symptoms as the result of this accident, may be altogether ignorant of the cause. Hamburger is cited by Riegel, in 'Ziemssen's Handbuch,' as having recorded a case of an old man aged seventy, who fainted after a journey, and was found in a state of dyspnœa, with evident obstruction of the right bronchus. An emetic was given, which led to the expectoration of a green pea swollen to the size of a bean; and afterwards it was learnt that when he was eating peas one day, something had gone the wrong way.

Symptoms of stenosis of the lower air-passages.—Of these the most important is *dyspnœa;* as contrasted with laryngeal stenosis that of the trachea is characterised by difficulty of breathing without loss of voice. One must, however, remember that the power of speaking well and even loudly is not in itself proof that the seat of an affection attended with severe dyspnœa is not in the larynx; for in bilateral paralysis of the abductors of the vocal cords precisely this combination of symptoms is met with, as has already been shown (p. 875). Moreover, it frequently happens that the voice in cases of tracheal stenosis is weak, thin, and devoid of sonorous quality, from deficiency in the stream of air reaching the larynx from below. A further point to be borne in mind is that syphilitic disease of the larynx is often combined with a like disease of the trachea; a patient may have lost his voice as the result of a syphilitic affection of the larynx, but the dyspnœa from which he suffers may nevertheless be dependent on mischief lower down, so that, if tracheotomy should be performed, the operation may turn out a failure. Again, in many cases of aneurysm or of mediastinal growth, tracheal stenosis is accompanied by paralysis of laryngeal muscles, as the result of pressure upon one or both of the recurrent laryngeal nerves.

Whether or not the voice is affected, it is therefore essential to make a thorough laryngoscopic examination in all cases of suspected stenosis of the trachea or of the main bronchi. Moreover, it is sometimes possible, especially if the larynx is healthy, to make a direct diagnosis of the nature of a tracheal lesion by examination with the mirror. The lower part of the windpipe, with its bifurcation and the orifices of the two bronchi, is said to have been first seen in the person of Czermak himself by Elfinger. Türck has described the conditions most favourable to a successful exploration of these parts. The patient should be seated with the body and the neck upright and the head bent slightly forward, the object being to bring the axis of the larynx and that of the trachea into a straight line. The mirror must be placed against the soft palate, rather further forwards than usual, and with its surface nearly horizontal. The observer should sit at a lower level than the patient. The illumination must be very bright, and the light should be thrown into the mouth horizontally, or rather from below. An aneurysm may sometimes be seen bulging into the trachea, as in a case of innominate aneurysm which was examined by Mr Lane when house physician at Guy's Hospital. It must not, however, be supposed that a mere slight pulsation of the lower end of the trachea necessarily indicates a morbid condition, for Gerhardt and Schrötter have shown that such pulsation transmitted by the great arteries is present in many healthy persons.

Local diagnosis.—An important distinction between stenosis of the lower air-passages and that of the larynx was first pointed out by Gerhardt It

is that in the former affection the larynx does not during inspiration make the rapid and extensive vertical movements which occur when the larynx is itself the seat of obstruction to the entrance of air. According to this observer, if with severe stenosis the range of descent of the larynx is not more than one centimetre, one may confidently assert that the disease is either in the trachea or possibly in both bronchi, but not in the larynx. He also remarks that the position of the patient's head differs in the two sets of cases. When the obstruction is laryngeal, the head is thrown backwards as far as possible. When it is tracheal, the head is stretched forwards, and the chin slightly depressed, so as to relax the trachea.

The dyspnœa in stenosis of the lower air-passages is in the main inspiratory, like that in laryngeal stenosis. It is less often extreme in degree, on account of the greater calibre of the trachea as compared with that of the glottis. Consequently the breathing is not usually much altered in frequency; nor are the lower ribs and the other unsupported parts of the chest walls very much sucked in. But should the disease go on to actual suffocation, all these phenomena may be as marked as they possibly can be.

There is generally from an early period the most noisy stridor, heard not only through a stethoscope over the trachea, but also more or less on auscultation over every part of the chest, so that it drowns the normal breath-sounds. Indeed, it is commonly obvious to everyone standing near the patient. According to Gerhardt, the only cases in which any safe conclusion as to the seat of the obstruction can be drawn from observing the spot at which this sound is heard loudest through the stethoscope are those in which this spot is directly over the trachea in the neck. When there is stenosis of the lower part of the trachea, it often happens that the sound is audible with greater intensity over the larynx than over the sternum. Sometimes a râle is constantly discoverable over some particular point in the trachea. A sign to which Demme has drawn attention is that in prolonged cases of constriction of the lower air-passages the circumference of the upper part of the thorax becomes lessened.

In most cases of stenosis of the trachea, the dyspnœa undergoes aggravation from time to time; there are paroxysms of extreme distress attended with cyanosis, and generally one of them at length proves fatal. It was formerly supposed that the cause of such attacks was paralysis, or perhaps spasm, of the vocal cords from implication of one or both of the recurrent laryngeal nerves; but Dr Bristowe, in an admirable paper in the third volume of the 'St Thomas's Hospital Reports,' showed that this is not the fact. They are probably due either to acute swelling of the mucous membrane at the seat of pressure, or to an accumulation of mucus there which cannot be dislodged, or perhaps in part to spasm of the muscular tissue of the trachea itself. It is important to notice that no relief is to be expected from the performance of tracheotomy.

The patient commonly complains more or less of oppression of the chest, of soreness behind the sternum, or of actual pain. There may or may not be cough, with expectoration of mucus, perhaps tinged with blood, according to the nature of the disease which produces the stenosis.

In contrasting the physical signs of obstruction of one bronchus with those of stenosis of the entire lower air-passages, the first point to be remarked is that much depends upon whether the obstruction is complete or partial. In the former case there is absence of vesicular murmur over the corresponding side of the chest, with impaired movement of the ribs and of

the diaphragm, deficient vocal fremitus, and a normal percussion-sound. After a time the side may actually be found to have fallen in, and to measure less than the other side. In the latter case a snoring, whistling, or humming sound may be heard over the root of the lung between the scapula and the vertebræ, or there may be moist sounds there. A thrill may sometimes be felt with the hand placed upon the surface of the chest.

One clinical peculiarity of the obstruction of a main bronchus caused by a foreign body is that it is far more sudden, as well as more complete, than that due to any other cause. Consequently its effects may be supposed to approximate more closely than in any other morbid condition likely to be observed in man, to those of the plugging of a bronchus by wedges of laminaria which were studied by Lichtheim in a series of experiments on rabbits recorded in vol. x of the 'Arch. f. exp. Pathologie.' The opposite lung in these experiments became enormously distended. Very often it gave way, so that pneumothorax resulted; and even when this did not occur the animal usually died within twenty-four hours. What proved that the rapidly fatal issue was immediately dependent upon the state of this lung rather than of the one which was deprived of air, was that death did not follow when the pleura was laid open on the side of the obstructed bronchus. A bean or a pea is capable of swelling, like the laminaria plugs used by Lichtheim, although more slowly; and his results are worth bearing in mind, because it may be that in the failure of all attempts to extract a foreign body from a bronchus, it might sometimes be justifiable to admit air into the pleura; even if the operation did not prolong life it might greatly relieve the dyspnœa.

Sequelæ.—Every form of disease producing obstruction of the lower air-passages is liable to be followed by inflammatory changes in the pulmonary tissue, as well as in the walls of the air-passages themselves. Thus when an aneurysm has pressed upon the trachea, or upon a bronchus, the mucous membrane has repeatedly been seen ulcerated, and some of the cartilages exposed and partially detached, even though there may have been no indication of an approaching rupture of the sac. Stenosis of a bronchus, from whatever cause, is not infrequently accompanied by dilatation of its branches within the lung. Purulent fluid is apt to accumulate in them, and the result is the occurrence of more or less extensive pneumonia, which often goes on to gangrene. A foreign body fixed in a bronchus often sets up ulceration and sloughing of the part of the tube against which it presses. Sometimes this ends in perforation of the pleura, with pneumothorax, and the foreign body itself may become loosened and fall into the serous cavity. Sometimes it leads to pneumonia, which may spread from the root of the lung far into its substance. The occurrence of fœtid expectoration, and the development of the physical signs of hepatisation may reveal these various changes, but in some cases they are first detected in the *post-mortem* room. Even after expulsion or removal of the foreign body, it sometimes happens that the case nevertheless ends fatally as a consequence of the pneumonia that had been set up; but happily this sometimes subsides, and the patient makes a permanent recovery.

With regard to the *diagnosis* from one another of the several affections that may cause obstruction of the lower air-passages, it is worth remembering that the two diseases in the course of which stenosis of the trachea is most apt to occur without the presence of any other symptoms are *syphilis* and thoracic *aneurysm*. When the obstruction is limited to a bronchus,

especially perhaps on the left side, aneurysm is still probable; a mediastinal growth is a more likely cause than a syphilitic stricture. The possible presence of a foreign body must never be forgotten, especially if the symptoms have come on suddenly.

The *duration* of syphilitic disease of the trachea after symptoms have set in ranges, according to Gerhardt, from two months to four years. That of stenosis from compression would probably be found to be confined within comparatively narrow limits of time. Foreign bodies sometimes remain for a very long period—for months, even for years—in the lower air-passages, and yet are after all expectorated.

As to the *treatment* of the various affections that may cause stenosis of the trachea or of the bronchi, there is little to be said. Whenever there is a possibility that it may be due to syphilis, mercury and iodide of potassium should be actively employed. Gerhardt relates, in vol. ii of the 'Deutsches Archiv,' the case of a man, aged thirty-six, who had had constitutional symptoms after a hard chancre eight years before, and who consulted him on account of cough with scanty muco-purulent expectoration, a tickling sensation behind the sternum, a little alteration of voice, and slight interference with the breathing. These symptoms had been present for about six months. The patient had lost flesh, and his face was somewhat puffy and livid. Nothing could be discovered with the laryngoscope, and only râles behind the manubrium with the stethoscope. A permanent cure was effected by the administration of full doses of iodide of potassium during several weeks. Unfortunately, however, the cases which are usually seen, where cicatricial bands and ridges have already been formed, appear not to be amenable to anti-syphilitic remedies.

When there is a foreign body in the air-passages, the only proper course is to perform tracheotomy at once. Until this has been done, it is not safe to place the patient head downwards on the chance that the body may fall out through the glottis, as happened (but after tracheotomy) in the case of Mr Brunel, which is so graphically told in Watson's 'Lectures.' Nor does it appear to be prudent to administer an emetic; for the body, if dislodged from its position in a bronchus, may become impacted in the larynx and cause suffocation.

DISEASES OF THE LUNGS

SYMPTOMS AND PHYSICAL SIGNS

"Who knows but that, as in a watch we may hear the beating of the balance, and the moving of the wheels, and the striking of the hammers, and the grating of the teeth, and multitudes of other noises—who knows, I say, but that it may be possible to discover the motions of the internal parts of bodies (whether animal, vegetable, or mineral) by the sound they make; that one may discover the works performed in the several offices and shops of a man's body, and thereby discover what instrument or engine is out of order."—ROBERT HOOKE, 1667.

THE modern era in medicine was begun in the seventeenth century on its theoretical side by Harvey, on its clinical side by Sydenham; but just as anatomy and physiology languished from the close of the seventeenth till the third decade of the nineteenth century, so medicine made slow and uncertain progress until the close of the war which followed the French Revolution. Indeed, certain facts known to the Greek physicians were unknown at the beginning of the present century.

In the fifty years between 1815 and 1865 three great advances were made in the clinical investigation of disease—the discovery of mediate auscultation by Laennec, the recognition of Bright's disease, and the invention of the ophthalmoscope and laryngoscope. To these may perhaps be added the discovery of the reaction of degeneration and the application of electricity to the diagnosis of nervous disorders—not to their treatment, for that was much earlier and far less important.

Of these advances the earliest and the most considerable was the introduction of the physical examination of the chest. This was not entirely unknown to the ancients, and Auenbrugger had made important steps in this direction.

The mere invention of a mode of listening to sounds within the chest might have remained a curiosity, and has more than once led to learned trifling; what made it fruitful was its association with morbid anatomy. The great merit of Laennec (as of Bright afterwards) was that he constantly followed up his researches in the wards by dissection in the deadhouse. Hence, notwithstanding his premature death (by one of the diseases which he elucidated), he left the main outlines of the detection of pulmonary diseases with few omissions to supply and fewer errors to correct.

PERCUSSION.—This method was discovered in the middle of the last century by a Viennese physician, Auenbrugger, who published in 1761 his '*Inventum novum, ex percussione thoracis humani, ut signo, abstrusos interni pectoris morbos detegendi.*' This method, however, seems to have been adopted by Stoll alone among contemporary physicians of eminence, and it had passed into complete oblivion when Corvisart, in 1808, brought out in Paris a translation of Auenbrugger's work, with commentaries of his own, based upon extensive practice at the Hôpital de la Charité. Percussion was adopted by Laennec, and introduced into this country in 1825 by Sir John Forbes.

The way in which Auenbrugger performed percussion was by striking the chest directly "with the tips of the fingers, brought close together and stretched out straight." He also directed that either a glove should be worn, or that the patient's shirt should be kept on, so as to avoid a slapping noise. Even now the bent fingers of one hand, with their tips brought to a level, are sometimes used to ascertain roughly the state of the back of the lungs; but for more delicate percussion such a method is inadequate.

In 1828 Piorry, who was afterwards physician in the Charité at Paris, published a work upon what he termed "mediate percussion." This consisted in the use of a thin plate of ivory called a *plessimètre*, to be held by the left hand in contact with the surface of the chest, while a tap was given to it with the tip of the right forefinger, or with the tips of the fore and middle fingers. A hammer, which is known as a *plessor*, was afterwards added. On the Continent these instruments are more or less employed, and they are sometimes useful for teaching a class without hurting the patient. But in this country the usual practice is to simplify Piorry's method by using the left fore or middle finger in the place of a plessimeter. It is curious that in his original work Piorry himself speaks of that plan as having been already adopted by certain English and American physicians who had attended his lectures.

It must not be supposed that percussion is easy. On the contrary, a great deal of practice is necessary to enable one to obtain correct results; and clinical clerks commonly continue to make blunders in percussing long after they have mastered the difficulties of auscultation. The blow should come from the wrist; it should be sharp and sudden, so as not to damp the sound which is produced, and the fingers at the moment of striking should be as nearly vertical as possible. The amount of force that should be employed, and the extent to which the finger should be raised before striking, vary with the thickness of the soft tissues over the part of the chest which is to be struck; and every physician, even without being aware of it, modifies his manner of percussing in different patients and upon different regions of the chest as experience has taught him, in order to elicit the best possible sound under various conditions. As a rule, percussion can be practised by a skilled observer without causing any sensation that is complained of by the patient as being painful; but in delicate women, and even in some very thin men, the sternum and the ribs may be so exquisitely tender that a satisfactory sound can be elicited only with great difficulty. Sometimes cough is excited by every attempt at percussion, and a forcible blow may even lead to blood-spitting, so that it is well to abstain as far as possible from this method of examination when there has been recent hæmoptysis. In such cases, and generally with children, it is better to begin with auscultation and inspection.

We must not imagine that in different persons one can always elicit the same sound by percussion of the chest if the organs are healthy; nor, again, that the sound ought to be the same over different parts of the same chest. But, in health, the range of percussion-sounds is almost limited to a simple series. One extreme is heard where a thick mass of solid tissue lies behind the ribs, as over the centre of the heart just below the fourth left costal cartilage, or over the liver between the right seventh and eighth ribs. This sound is said to be "flat" or "dull."* It is, however, less absolutely dull than the note which is heard on percussion on the fleshy mass of the forearm or thigh, and seldom so dull as the note obtained by percussion over a solid lung or liquid effusion in the pleura.

The other extreme is heard where the ribs cover a thick substance of lung, as in front below the clavicles, in the axillæ, or behind below the scapulæ. This sound is commonly called "clear" or "resonant."† Both sounds are difficult to describe, but they are easily recognised in practice.‡

Between the extremes of dulness and resonance there are all gradations, for which the expressions "partial dulness," "incomplete resonance," "muffled resonance," are employed. These varieties of percussion-sounds are heard at the borders of a resonant or dull area, especially where the lung overlaps a solid organ with a thin edge. At such points many different sounds are obtained, according to the amount of force used in striking. A gentle blow elicits a sound only from the parts immediately below the spot which is struck; a more forcible blow affects deeper parts as well. Thus it is usual to speak of "superficial" and of "deep percussion." But it must be remembered that in "deep percussion" the sound is also modified by the structures which are laterally adjacent, so that a resonant area interferes with the sound yielded by a dull area on forcible percussion, although a dull area does not interfere with the sound yielded by a resonant one. For example, by "deep percussion" over the heart one can often elicit a more or less resonant sound even when it is not covered by lung; but on deep percussion over the lung it is not possible to detect any degree of dulness, however slight, as the result of the presence of the heart or of the liver by the side of the lung. When a solid organ is overlapped by lung, it is often necessary to employ deep percussion as the only means of detecting the distance to which the solid organ extends. But under other circumstances superficial percussion should be used when the object is to map out the relative positions of the viscera. It is otherwise when one wishes to determine the presence or absence of disease of the pulmonary tissue. In such cases one has to ascertain by repeated trials what amount of force is necessary to bring out an altered percussion-sound most distinctly.

As a rule, it is by comparing the two sides of the chest together in the person under examination, rather than by an absolute standard, that one judges of the results obtained by percussion. But if both sides are diseased this method may altogether fail; and even when only one side is diseased it is necessary to have some kind of standard, since without it one could

* Dulness on percussion: *Sonus obscurus; Fr.* Matité; *Germ.* Dämpfung.

† Resonance on percussion: *Sonus clarus; Fr.* Son clair; *Germ.* Sonorer oder heller Schall.

‡ It is important to bear in mind that "resonance on percussion" means altogether a different thing from what is called *resonance* in acoustics. This conventional way of using a scientific term would no doubt have been better avoided, since it is apt to lead to confusion; but in England it has been universal, and can scarcely now be altered.

not tell, by percussion alone, on which side the disease lay. Now, as already stated, the percussion-sound in health is different in different individuals. The thinner a man is, the more "resonant" his chest is likely to be; in very muscular or very fat persons it is sometimes difficult to elicit a clear sound anywhere, particularly over the backs of the lungs.

The differences in percussion-sound at different parts of the chest in health depend upon obvious anatomical conditions, but they nevertheless require careful study in actual practice. In front the sound is modified by the position of the liver and of the heart on the right and left sides respectively; and immediately below the clavicles it is more resonant near the sternum than it is further outwards. Behind, in the supra-scapular regions, one sometimes has to use a good deal of force in order to elicit anything but a dull sound and even between the scapulæ the sound generally becomes gradually more resonant as one passes downwards. Below the scapulæ the sound is generally almost as clear as under the clavicles; the resonant area on the left side extends about a finger's breadth lower than on the right side where the liver encroaches on the thorax. While the back is being percussed the patient should have his shoulders drawn forwards as much as possible, crossing his arms over the chest. In this way the "interscapular region" is increased and the "scapular" regions are much diminished.

Since the infra-clavicular regions are frequently the seat of phthisis and the basal regions of pneumonia or pleural effusion, the axillæ are the safest regions for obtaining the normal resonance of the lungs in any individual case; and the right side is preferable, because a distended stomach sometimes gives a tympanitic quality to the axillary note on the left.

We said that the variations of the percussion-sound in health are *almost* limited to a simple series. The qualification was necessary for two reasons. When the sternum, the clavicle, or one of the ribs is struck, a high-pitched tone is added to the sound, giving it what is termed an "osteal" character. In an infant, especially when it is screaming, one sometimes elicits what will presently be described as a "cracked-pot sound."

With regard to the theoretical interpretation of percussion-sounds there have been great differences of opinion. Even now scarcely any two writers seem to express the same views; and the variations in nomenclature are most confusing. Dr Walshe insists that the use of the terms "dull" and "resonant" (or "clear") is inaccurate, because they represent conditions which, instead of being "simple, are in reality made up of several elements, capable of separate analysis." But the analysis which Dr Walshe himself has attempted throws less light on the subject than we might expect. The view which appears the most satisfactory—if we may assume its theoretical accuracy, as to which few are competent to form an opinion—is that stated by Dr Gee. He declares that the terms in question are capable of scientific definition. According to him, dulness means *absence of tone;* a part is dull when the sound which it yields on percussion is a mere noise, without that regular succession of vibrations which constitutes tone. On the other hand, varying degrees of clearness or resonance correspond with the admixture, in different proportions, of noises and tones. No percussion-note is ever perfectly pure; and thus, beyond the resonance yielded by the healthy chest of even the thinnest person, there are "over-resonant" sounds which may accompany certain diseases.

Another question upon which writers differ is as to the seat of the vibrations causing the tone which is elicited by percussion over the healthy chest.

Dr Gee refers this tone to the middle-sized and largest bronchia; following Wintrich, he thinks that the pulmonary vesicles and the bronchioles are too small to yield it. But it certainly seems to be a great obstacle in the way of the acceptance of that view that in bronchitis resonance is seldom, if ever, impaired, however completely the tubes become filled up with pus or mucus. At least the *noise* or toneless part of a percussion-sound must, one would think, be due to vibrations of the thoracic walls, seeing that its amount, in proportion to that of the tone, varies with their thickness and with the extent to which they are loaded with fat; and Dr Bristowe believes that the whole of a percussion-sound is "mainly due to the vibration of the thoracic walls alone." He assumes that "so much of each half of the thorax as bounds lung-tissue vibrates bell-like when any part of that half is struck; and that the impure musical sound which is elicited comprises a fundamental tone due to the vibration of the whole or a large portion of the side, and harmonic tones due to the vibration of aliquot parts of it." It is a strong argument in favour of this doctrine, that deformity of the chest, without any apparent thickening of the parietes, may give rise to absolute dulness on percussion, notwithstanding that the lung beneath is quite healthy: when there is lateral curvature of the spine, for example, the rounded projection formed by the ribs on one side of the back generally yields a dull sound. Another argument is afforded by a peculiar alteration in the percussion-sound beneath the clavicle, known as Skoda's resonance, which is observed when a certain quantity of fluid is present in the corresponding pleura. For no explanation seems so satisfactory as that suggested by Dr Bristowe, namely, that the vibrating area is diminished, and that consequently it yields a fundamental tone which is raised in pitch. But the subclavicular percussion-sound is not affected in the same way when there is pneumonia of the lower lobe of the lung. So that one must assume, on Dr Bristowe's view, that hepatisation of the lung, notwithstanding that it gives rise to a more or less dull sound when percussion is made directly over it, does not, like pleural effusion, completely damp the vibration of the corresponding part of the chest wall and prevent it from joining with the rest of the side in emitting a tone when a distant part is struck.*

We have already spoken of the chest as being sometimes *over-resonant*—a better term than *tympanitic*, which has often been employed as meaning the same thing. Originally a percussion-sound was called tympanitic (*i. e.* like the note of a drum) when it was such as would be yielded by an abdomen in which the intestines are distended with gas; for tympanites has, since before the days of Hippocrates, been a name for that condition. And, as a matter of fact, the sound generated by percussion over an emphysematous (or over-distended) lung, when the chest walls are rounded and thin, often approaches, if it does not actually reach, this tympanitic quality.

Dr Gee classifies percussion-sounds containing adventitious tones as follows, according to their *pitch*. Those which are highest pitched he calls *Osteal*, after Piorry, because they are yielded by the hard solid tissues, cartilage,

* One point, however, in which it is less easy to agree with Dr Bristowe is his rejection of the distinction between "superficial" and "deep" percussion. He evidently thinks that his doctrine is incompatible with the admission that a percussion-sound can in any way be modified by the presence of solid matter within the chest, except in so far as it is in direct contact with the inner surface of the chest wall. But about the reality of this distinction there is surely no doubt.—C. H. F.

and bone, as has already been mentioned. Those which are somewhat lower were termed by Dr C. J. B. Williams *Tracheal* or *Tubular*, being more or less like the note yielded by the trachea on percussion when the mouth is a little open. Lower still are tones which Dr Gee proposes to call *Subtympanitic;* they are such as are usually yielded by percussion over healthy lungs in their natural state of distension. The lowest pitched tones of all are the *Tympanitic*, and are heard on percussing the healthy abdomen.

Certain modifications of the percussion-sound are noticed under special circumstances; they are the "amphoric note" and the "cracked-pot sound."

The *amphoric percussion-note** is described by Dr Gee as consisting in an "overtone existing either apart and alone, or as an harmonic superadded to the fundamental tone, which itself may either be clear or muffled." It is commonly heard when percussion is made over a stomach distended with air. It may also be elicited by giving a sharp fillip to the cheek when it is blown out to a certain point. It is higher in pitch than an ordinary tympanitic note.†

The *cracked-pot sound*‡ is exactly like the chinking of coins, or the sound produced by clasping the hands loosely together and striking them upon the knee. Probably it always depends upon the propulsion of air out of a space through a more or less narrow opening. It was originally noticed by Laennec, who gave it the name of *bruit de pot fêlé.*

Lastly, it must be stated that, besides the sound which is yielded by percussion and is audible to bystanders, the physician is himself conscious of differences in the tactile sense of resistance offered to his fingers as he taps, and that this is often of considerable assistance in enabling him to draw correct inferences from his observations.

As to the *practical significance* of the various modifications of sound elicited by percussion of the thorax, it is not necessary to say much in this place, since the subject must be considered in discussing each of the diseases of the bronchi, of the lung, and of the pleura. But, in general, it may be laid down that *dulness* on percussion may mean either consolidation of the pulmonary tissue, or its compression and solidification by fluid or otherwise. As a rule, the diagnosis between the causes of a dull note is based upon several considerations independent of percussion. But the dulness resulting from the presence of liquid in the pleura has the peculiarity of being more complete or absolute than that which arises in almost any other way; and the sense of resistance is also greater, especially when the quantity of liquid is large.

A *tympanitic sound* is either due to extreme emphysema of the lung, or, if typical, depends on the presence of air in the pleural cavity. There is, however, a very rare affection, diaphragmatic hernia, which may simulate left pneumothorax by escape of the stomach through the diaphragm into the chest. Moreover, a distended stomach may push up a shrunken lung until what appears to be thorax yields a tympanitic note.

The various combinations of dulness with tympanitic, subtympanitic,

* *Fr.* Son argentin, son métallique, son humérique; *Germ.* Metallklang, Amphorischer (d. h. krugartiger) Schall, metallish-klingender Schall.

† As a drumhead is tightened, its note when struck becomes shorter and shorter and also higher and higher in pitch, but it never loses its resonant ("tympanitic") character which distinguishes it from that produced by striking a solid object.

‡ *Fr.* Bruit de pot fêlé; *Germ.* Zischender oder klirrender Schall (Geräusch des gesprungenen Topfes).

tracheal, and osteal tones are met with chiefly when there are cavities or vomicæ in a part of the lung which is separated from the surface by a thickened and adherent pleura or by a layer of consolidated pulmonary tissue, or when air is present in a pleural cavity of which the walls are indurated. The significance of the amphoric ring and of the cracked-pot sound will be fully considered elsewhere.

Before leaving the subject of percussion it is well to repeat that the student who aims at more than educating his ear to appreciate differences of sound, and learning their empirical significance, must remember that "dull," "resonant," and "tympanitic" are conventional terms, best defined, practically, as those elicited by percussion over the forearm, the right axilla, and the stomach respectively; but that each of these sounds, and the many others to be heard by percussion of the healthy as well as of the diseased body, consist of a fundamental tone with endlessly varied harmonic or discordant overtones, and that each note may vary as follows: (1) in loudness or amplitude of vibrations; (2) in pitch or number of vibrations per second; (3) in duration; (4) in quality or *timbre*.

A clear sound (*son clair*, *heller Klang*) is opposed to a non-resonant or toneless one (*mat*, *dumpf*), and a high or treble to a low-pitched or bass; a tympanitic note, on the one hand, to an osteal or sternal sound which, though resonant, is high and very short, and, on the other hand, to a long but completely toneless one; and lastly (according to Skoda), a loud and long percussion-sound (*voller Schall*) to a short and feeble one of somewhat high pitch (*leer*).

This is the most convenient place to mention an effect of "immediate" percussion, which is not infrequently seen in emaciated persons, namely, the production of contractions in muscles which receive the tap, especially in the pectoralis major. A rounded knot rises up at the spot which is struck, and from this a smaller ridge spreads away, wave-like, along the fibres in both directions. This "idiomuscular contraction" has been supposed to be characteristic of phthisis; but it occurs in most wasting diseases, when the muscles are in a condition of physiological "exhaustion."

AUSCULTATION.—As Dr Gee remarks, it is an interesting fact that this, a still more important method of physical examination than percussion, arose directly out of Corvisart's researches. Among those who followed the practice of that professor at the Paris Charité were two friends, Bayle and Laennec. In endeavouring to distinguish between active and passive enlargement of the heart when percussion showed its size to be increased, they were in the habit of carefully observing the character of its impulse; and they became accustomed to apply the ear to the cardiac region for this purpose rather than the hand. One day (about 1815) Laennec was consulted by a young woman who had the general symptoms of disease of the heart, but in whom, as she was fat, he was unable to feel the impulse satisfactorily. For reasons of delicacy he was hesitating to put his head to her chest, when he remembered the fact that by applying the ear to one end of a plank one can hear the scratch of a pin at the other end. So he took a quire of paper, and rolled it very tight. And then, placing one end on the precordial region, and leaning his ear on the other end, he found, to his surprise and pleasure, that he could actually hear the beating of the heart more plainly than when the ear was in immediate contact with the thoracic wall. He soon began

to employ the new method of investigation, which he termed *l'auscultation médiate*, in phthisis and other pulmonary diseases, read a memoir on the subject in 1818, and published his great work in the following year. In 1826 he died of phthisis, at the age of forty-five, having almost worked out the subject so far as concerns affections of the lung.

Appreciating the importance of combined percussion and auscultation, Laennec was also well acquainted with the morbid anatomy of the diseases to be recognised. He showed how to distinguish by physical signs pneumonia, emphysema, pleuritic effusion, and pneumothorax, and he classified and defined the most important variations of the respiratory murmur as well as the chief adventitious sounds to which he gave the general term *râles*. He, like other pathologists at that time, was not aware of the importance of bronchitis (*catarrhe pulmonaire*) as a separate disease, and the very term was still unused; but he described the signs of œdema of the lungs and of phthisis almost as we should describe them now, and pointed out the existence and significance of the curious sound called "metallic tinkling."

It is remarkable that of the very few references to sounds heard by listening over the chest which have been traced in medical writings of an earlier date, two are in the works of Hippocrates, the father of medicine; he mentions the leather-like creaking of pleural friction and the splash obtained by succussion. The only other notice of any sound produced in the lung is, according to Dr Gee, one of pneumonic crepitation in van Swieten's 'Commentaries,' published in 1774.

The stethoscope.—In examining the backs of the lungs we still sometimes apply the ear directly to the surface of the chest, or rather so that only a towel or the patient's night-dress separates one's ear from his skin. In this way one can rapidly judge of the state of a large part of each lung; and it is often more convenient than using an instrument when the person is very ill and has to be lifted up in bed by attendants. But in most cases we employ some form of stethoscope. That which was originally designed by Laennec (*le cylindre*) has long ago been discarded; it was long and heavy, in shape like a general's leading staff or a thick and short ruler, and it was needlessly elaborate in construction.* What is now used is generally a light hollow stem of wood or metal, having a flat ear-piece at one end and spread out into a concavity at the other end, which is placed upon the spot to be examined. In applying it one must be careful not to hurt the patient by pressing too hard or by bearing unevenly upon one side of the rim. The ear must always be moved to the stethoscope, and not the stethoscope to the ear. There is no object in the perforation except for lightness; the sound is conducted by the solid substance, not by the column of air. A very light stethoscope and one made in two parts is so far faulty; a somewhat massive form made in cedar is acoustically better.

Many years ago a stethoscope was introduced in which the chest-piece and an ear-nozzle were connected by a flexible tube, and it is still used by some good auscultators. It is extremely portable, and as convenient as the binaural form for auscultation of the sides and back of the chest without raising the patient.

Recently, however, it has become the fashion to employ a stethoscope with a flexible stem and with two long metal and ivory ear-pieces, one of which is

* The specimen in the Royal College of Physicians in London is about ten inches long and rather more than an inch thick. It is perforated and divided into three parts, so as to make it half the length if desired, and to allow the "obturator" to be taken out or left in.

introduced into the meatus of each ear, and is held in position by an elastic band. To the use of this double or binaural stethoscope, as it is called, everyone should accustom himself, because of the facility with which the back and sides of the chest can be explored by it in persons who are too ill to sit up. Students like the instrument on account of the loudness with which sounds are transmitted through it. But it is not certain that what reaches the ear is always as clear and distinct as when a single stethoscope is employed. And the slightest movement of the flexible part of the binaural stethoscope produces noises which are apt to be perplexing. Other disadvantages of the instrument are that it is cumbersome to carry about, that the least contact with the patient's dress causes a loud noise, that it is almost useless unless applied directly to the skin, and that the natural sounds, as estimated by immediate auscultation, are exaggerated. Its advantages are its convenience of application to many parts of the chest, the exclusion of other sounds by both ears being occupied, its allowing the auscultator to see while he is listening (not always an advantage), and its making both respiratory and cardiac murmurs easier to hear.

The double stethoscope is best used to determine the existence and character of slight or doubtful cardiac murmurs; it is useful for listening to the trachea and vessels of the neck, to the lungs above the scapulæ, and to the abdomen, and it or the single flexible stethoscope is almost indispensable for listening to the lungs of a recumbent patient.

For examining the heart and the front of the chest without removing a patient's underclothing, the ordinary wooden stethoscope is the most suitable instrument.

For listening to the back of the lungs while the patient is standing or sitting up in bed, no form of mediate auscultation is so convenient as the application of the ear to the patient's chest covered by a thin towel.

Whatever form of stethoscope may be employed, one must take care that the patient's clothes do not rest against it nor against the surface of the chest near the spot to which it is applied. And another point to be kept in mind is that if the instrument is placed on the hairy part of a man's chest a crackling sound is often produced which may be very like what will be presently described as crepitation. This difficulty may be avoided by wetting the surface or smearing a little oil over it.

AUSCULTATION OF THE BREATHING.—*The respiratory murmur and its modifications.*—On listening over the lungs of a healthy person, one hears each time he breathes a soft, rustling, breezy sound, followed by a second one of similar quality but of shorter duration and fainter. Of this no further description is needed, since the only way of really learning to know it is to hear it again and again and in many different individuals. It is commonly called the "*vesicular murmur*," having been so named when the idea that it arose in the air-vesicles of the lung was accepted without question; but such an association with a theory which is disputable is an objection to the term. Dr Walshe proposed "pulmonary respiration-sound" instead. "The normal *respiratory murmur*" is perhaps a still better term.* The former part of this sound accompanies the act of inspiration; expiration is either altogether noiseless or attended by the shorter and fainter murmur, almost continuous with the inspiratory.

In some persons the respiratory murmur is much louder than in others.

* *Fr.* Souffle respiratoire, souffle vésiculaire; *Germ.* Normaler Lungengeräusch.

In children it is particularly loud, so that when under morbid conditions an equally intense murmur is heard in an adult, this is sometimes called "puerile breathing." But in thin adults it is often scarcely less loud, even when all parts of the lungs are healthy. On the other hand, there are some people in whom the act of breathing is attended with scarcely any sound, even when one tries to make them breathe deeply. One must therefore listen over different parts of a patient's chest before one draws conclusions from the degree of loudness of the murmur at a single spot. It is naturally louder where the thoracic walls are thin than where they are covered with thick muscular masses, and over the edges of the lung it is less loud than elsewhere; in other words, its intensity in health is generally proportionate to the degree of resonance on percussion at various parts of the chest. In the same way it is feeble when the walls of the chest are thickly covered with fat.

At the bases of the lungs, especially in persons who are confined to bed by whatever cause, the vesicular murmur is sometimes found to be mixed with a crackling sound, which may be mistaken for crepitation, but which disappears when the breath is drawn deeply two or three times in succession, so that it must be due to slight collapse from disuse, and has no clinical significance. On the other hand, there are certain spots at which in many healthy persons the breathing is attended with a sound that differs from the vesicular murmur. They are (1) the space between the scapulæ over an area of variable extent, but somewhat lower in situation on the left side than on the right; (2) the region below each sterno-clavicular joint, especially on the right side and in females, and the part corresponding to the spines of the seventh cervical and first dorsal vertebræ. The sound heard over these parts is harsh, or, as it is often called, "*bronchial* in character," because it is transmitted from the main bronchi. It differs from the vesicular murmur in having a blowing character, in the expiratory part being as loud as the inspiratory, and in there being an interval between them. A similar sound is heard more loudly and constantly on auscultation over the trachea, and still more loudly over the larynx; here it is of a more "whiffing" quality and harsher, and is distinguished as "*tubular*," a term, however, which some writers use as synonymous with bronchial.

To be able, in practice, to distinguish a loud or harsh vesicular murmur from true bronchial breathing is the most essential step in auscultation. For the latter sound, with certain modifications of it, may be heard, in disease, over any part of the chest, and constitutes one of the chief signs of the most important pulmonary affections. In bronchitis, indeed, bronchial breathing does not occur, but it may accompany any disease in which the lung is either compressed, or consolidated, or hollowed into cavities. In other words, its range is generally conterminous with that of percussion-dulness. The modifications of bronchial breathing concern its quality. A blowing character belongs to them all; and they all consist of an inspiratory part and of an expiratory part, separated by an interval. What distinguishes them is that the blowing sound is more or less hollow. In its most extreme form it has an echoing character, and resembles the sound produced by breathing into a large empty glass bottle; it is then named *amphoric*.* When it is whiffing but without a "hollow" quality it is by

* A less marked degree of the same quality of sound is often called *cavernous*, because it is commonly heard over vomicæ, which are sometimes spoken of as caverns in the lung. The term is superfluous and misleading. A vomica may often yield consonating râles, not

most writers termed *tubular*, although others, as above mentioned, employ "tubular breathing" and "bronchial breathing" indiscriminately.*

It must be understood that between these several modifications of bronchial breathing all gradations exist, so that it is often difficult to know whether to call a sound "tubular" or bronchial, tubular or "amphoric." But it is well to maintain as far as possible the distinctions between them. If true tubular (or amphoric) breathing is heard, at whatever part of the chest, there can be no doubt that disease is present, even though the spot is one in which bronchial breathing is sometimes audible in health. It is a good rule to spare the more striking epithets. The usual errors of beginners are to mistake a loud or harsh respiratory murmur for bronchial breathing, to call bronchial breathing tubular, and tubular breathing amphoric.

With regard to the physical causes of the vesicular murmur, of bronchial breathing, and of its various modifications up to amphoric, there has been much speculation. Of late the tendency has been to apply to them strictly the theory of the *veine fluide*. According to this theory, a blowing sound is generated whenever a fluid (whether liquid or gas) passes from a narrow space into a wider one. Now, during inspiration this condition is fulfilled at two points in the respiratory tract: (1) when the air enters the trachea from between the vocal cords; (2) when it emerges from the extremity of each bronchiole into the ampulla formed by the air-sacs around. On the other hand, during expiration, the only point at which a *veine fluide* can be formed is at the upper orifice of the larynx; but since the false vocal cords form a lip on each side, the resulting sound should be audible not only above the spot at which it is formed, but also below. It is obvious that these facts accord perfectly with what has been stated with regard to the characters of the vesicular murmur and of the sound heard on listening over the trachea and primary bronchi. The former belongs mainly to the act of inspiration; the latter is divided into more or less equal parts, of which one attends inspiration and the other expiration. That the vesicular murmur is generated somewhere below the larynx has indeed been demonstrated in a series of experiments, of which an account was given by the author in the 'Med.-Chir. Review' for July, 1873, by certain French observers, especially Bergeon, Chauveau, and Boudet. They cut through the trachea of a horse and drew the lower end of the tube outwards through the wound in the skin, so that no *veine fluide* could possibly arise in it; after this operation they found, on listening over the animal's chest, that the vesicular murmur still remained audible, and that its intensity was little if at all diminished. On the other hand, by dividing the pneumogastric nerves in another horse they succeeded in abolishing the vesicular murmur. The explanation of this is supposed to be that the muscular walls of the bronchioles were paralysed, so that they opened into the air-sacs by wide funnel-shaped mouths—which would yield no *veine fluide*. In this last experiment the laryngeal sounds heard over the trachea are of course still persistent.

amphoric breathing at all. Moreover, the names of physical signs should refer to their physical characters, and not to the anatomical conditions they denote, especially when their significance is not constant.

* *Fr.* Souffles bronchique, bronchillaire, tubaire, glottique, soufflante, caverneuse, amphorique; *Germ.* Bronchialgeräusch, amphorisches Athemgeräusch. *Unbestimmtes Athemgeräusch* answers to the "vesiculo-tubular or subtubular" breathing of some English and the *respiration rude broncho-vésiculaire* of some French authors.

The theory of the *veine fluide*, however, in the form in which it is stated by the French experimenters, does not account for the fact that in most persons expiration is attended with a murmur, although a faint one. Moreover, in pulmonary emphysema the expiratory murmur becomes greatly prolonged and very noisy, while the inspiratory murmur is much diminished.*

The French observers whose views have been quoted suppose bronchial breathing, whether in health or in disease, to consist of sounds generated in the larynx, and transmitted downwards with more or less modification until they reach the ear of the auscultator. Indeed, they seem to have proved this experimentally. A horse was affected with pneumonia, and an intense *souffle tubaire* was audible. Chauveau and Boudet cut through the trachea, so as to allow air to enter the lungs without passing through the glottis, and the *souffle* at once disappeared. It would be of great interest to observe the same point in man, either in cases of cut throat or after tracheotomy; but the requisite conditions can scarcely ever be satisfactorily fulfilled, for unless the orifice into the trachea is as wide as the calibre of the tube itself a *veine fluide* may always be generated, at least during inspiration. Stokes, however, long ago pointed out that when the larynx is diseased it is often difficult or impossible to determine whether the lungs are or are not healthy. And it certainly seems very probable that extensive ulceration, destroying the attachments of the vocal cords, may prevent the formation of a *veine fluide* in the air which passes the glottis, and so render impossible the development of bronchial breathing in diseased lung below.

Of the modifications of bronchial breathing, from tubular to amphoric, all that need be said in this place is that the more marked the hollow quality the more one is justified in asserting that a space filled with air, of larger size than even a main bronchus, has been formed in the substance of the lung—unless, indeed, the pleural cavity itself should contain air. But even in acute pneumonia, when there has not been the slightest destruction of pulmonary tissue, it is surprising how hollow the bronchial breathing sometimes is; and Dr Walshe speaks positively of having heard sounds to which he would assign the name of "cavernous" in cases, whether of pneumonia or of pleurisy, in which there was no excavation, and in which the lung was only consolidated or compressed over large bronchial tubes.

Adventitious respiratory sounds.—The sounds derived from auscultation hitherto described have been sounds which are identical with, or more or less modified from, those that can be heard on listening over the healthy lungs or air-passages.

There are other sounds which are adventitious, and have no physiological representatives. Thus in pleurisy a *friction-sound* is heard, which has its origin on the surface of the lungs; this will be discussed in the chapter on pleurisy. With regard to the adventitious sounds which are found within the lungs there has unfortunately been much confusion of names. Some writers describe them all indifferently, either as "Râles" or as "Rhonchi;"

* These difficulties may be met as follows. It is a very slight extension of the results obtained by Bergeon, in experimenting with a tube provided with a lip or rim where it was narrowed, to assume that a lip, at the orifice of a contracting cavity, would generate a *veine fluide* in the cavity itself. Now, in emphysema it is fair to suppose that the mouth of the bronchiole projects some distance forwards into the space formed by the dilated air-sacs around it; and even under normal conditions it may do so sufficiently to produce the faint expiratory murmur which is heard in healthy persons.—C. H. F.

the former term was introduced by Laennec, and rendered into English as "rattle" by those who introduced his views into this country; the latter is used as synonymous in Germany. According to this use of the words, each is applicable indifferently to two kinds of sounds, which are very unlike one another, and which may be distinguished by those of the one kind being *continuous* and blowing, whereas those of the other kind are *interrupted*, and "crackling" or "bubbling" in character. Very often the two kinds are spoken of as being respectively "dry" and "moist;" but this is better avoided, for reasons which will presently appear.

There is, however, another meaning of the term *rhonchus*,* which seems to have been given it by the late Dr Latham, of St Bartholomew's Hospital, and which afterwards was sanctioned by Sir Thomas Watson. In that sense it is limited to continuous or "dry" sounds, or even to a single variety of dry sound. This is what is called sonorous rhonchus, the other dry sound being aptly termed *sibilus* or sibilant rhonchus. Both these sounds belong mainly to bronchitis. *Stridor* is a rhonchus so loud as to be audible at a distance.

If the two continuous (or "dry" and blowing) sounds are to have each a name of its own, the term *râle*† may conveniently be confined to interrupted ("moist" or crackling and bubbling) sounds. They occur in almost every disease to which the lungs or the air-passages are liable. They are generally attributed to the disturbance of fluid lying in the bronchial tube by air bubbling through it; and on that account they are called moist sounds. Each crack is supposed to denote the bursting of a bubble. But there have long been observers who maintain a different opinion, and ascribe them to the sudden separation of surfaces that had been in contact. In 1871, Traube, in the 'Berliner med. Wochenschrift,' applied this view to explain the râles heard in the larger tubes by the momentary detachment of portions of viscid mucus from their sides, by the current of air in respiration. It is difficult to conceive that in such thick secretion as is often found in the air-passages bubbles can be made and broken with sufficient frequency to account for the abundant râles that are often heard; and, as Traube remarks, râles are often to be heard in cases of pleuritic effusion, when there is not the least reason to suppose that any fluid is present in the tubes, and when therefore they can only be attributed to the separation of the sides of tubes that had been forced against one another in compressed parts of the lungs. He says that he has several times determined the absence of fluid in such cases at an autopsy. A further point to which he draws attention is that a râle can be produced by pressing gently with the stethoscope upon the surface of a healthy lung of a recently killed animal. Wintrich has shown that a like result may also be brought about by inflating the collapsed lungs after death ('Virchow's Hdbh.,' Bd. v, Abth. 1).

If Traube's explanation is correct, it will also apply to the moist pleuritic and pericardial rubs which closely resemble "mucous râles." There is, however, no doubt that the larger "bubbling" râles are produced by bubbles bursting either in the bronchi or the trachea.

Râles are somewhat arbitrarily distinguished according to the supposed size of the bubbles which produce them, or rather of the spaces in which they are found.

* Rhonchus (ῥόγχος or ῥέγκος, snoring) is Laennec's *râle crépitant sonore; Germ.* Knarren, Schnurren.

† The French word râle or *rasle* corresponds to the German *Rasseln*, and our *rattle*.

The gradation is sometimes made thus: *fine* (or small)—*submucous*—*mucous* râles, and then *gurgling;* but "mucous" is a bad epithet, for the fluid causing the râle may be pus or blood. "Small," "medium," and "large" râles are sufficiently descriptive terms.

In some cases râles, like rhonchi, are audible without the aid of the stethoscope. In fact, the "rattle in the throat" is only a large mucous râle.

Consonance.—There is another distinction between different kinds of râles which is of far greater importance than that of their apparent size, for it indicates whether the tubes in which they are found are surrounded by spongy or by solid lung. In the latter case they have a peculiar quality which in the former is wanting, and which the ear easily recognises, although to describe it in words is difficult. We may call the râles heard when the lung is solid "bright," "clear," "musical," "ringing," or "metallic." Skoda called them "consonating" râles, but we must not assume that their peculiarities depend upon *consonance* in the strict acoustic sense of the term (p. 840, *note*).

Consonating râles are associated with bronchial or tubular breathing, with dulness on percussion, and with the equivalent vocal sign called bronchophony.

The sounds which are termed crepitant râles (or crepitation) and subcrepitant râles are "smaller" (*i. e.* the interruptions are more frequent and shorter) than those of gurgling; and they differ from toneless or non-consonating râles of the same "size" or degree by their "bright" or metallic quality. One particular kind of râle, almost (if not quite) peculiar to an early stage of acute pneumonia, is termed *fine crepitation.* This sound is consonating and typically bright or musical, and it is never perfectly heard except when the lung is hepatised. It sounds less "moist" than any other râle. It will more fully be described and its origin discussed hereafter.

Non-consonating râles, chiefly heard in bronchitis, need no further designation than large, small, or medium.*

AUSCULTATION OF THE VOICE.—If, while listening to the chest of a healthy man, we tell him to speak, we generally hear an indefinite humming or buzzing noise. In a woman the sounds come to the ear more sharply, but one is still unable to distinguish the words that are uttered. Only over the upper part of the interscapular region on each side is there in some persons a space in which one can hear the voice clearly, and in which the separate words are perceived almost as they are when one places the stethoscope over the larynx and trachea, though less loudly.

* To every simple classification of râles and rhonchi that has as yet been proposed there are two insuperable objections. One is that in endeavouring to convey to other persons definite ideas as to the auscultatory phenomena observed in a case of pulmonary disease, or in receiving from them the same kind of information, we are at once baffled by uncertainty as to the sense in which we or they employ different terms, unless we are familiar with the various meanings that are assigned to them by practical men. The other objection is that in studying medical literature, as soon as we pass beyond the scope of a single text-book we fall into the gravest mistakes if we imagine that the language used by different writers has always the same sense. And as for the future, all experience goes to show that if the most distinguished physicians of the day were to meet week after week until they adopted a uniform terminology, and agreed to impose it on others, nearly every one of them would within a year forget in his own practice to make use of it.—C. H. F.

The attempt was made at the International Medical Congress at Copenhagen in 1884, with what degree of success remains to be seen.

Now, in disease the voice may be carried to any part of the chest thus distinctly, and may be heard far more loudly than is ever the case in health. For this "increased vocal resonance," as it is often termed, Laennec invented two names according to its degree of intensity. When the voice, however distinct, gave the impression of still coming from a distance he spoke of "*Bronchophony*;" when it appeared as though it were spoken from the chest immediately into the stethoscope he used the term "*Pectoriloquy*."*

Bronchophony, as a rule, is associated with bronchial or tubular breathing or with consonating râles; pectoriloquy with tubular or amphoric breath-sounds, or with metallic gurgling. In other words, bronchophony attends those conditions in which the pulmonary tissue is solid; pectoriloquy is heard when, in addition to solid lung, there is a large empty cavity. Occasionally tubular breathing and bronchophony may be heard over a part of the lung consolidated by pressure of fluid in the pleura.

Laennec laid more stress upon auscultation of the voice than of the breathing; the first section of his great work is headed "Exploration de la Voix." Pectoriloquy was the firstfruits of his great discovery, and he did not introduce the term bronchophony until after the first edition of his work; hence, as Dr Gee remarks, it is not surprising that he always clung to this sign with peculiar affection. It became his object to define it in such a way that it should become an unerring indication of a vomica. For this purpose he added to the characters of what he termed perfect pectoriloquy that of being limited to a very small part of the chest. But subsequent experience has shown that, like other "hollow" sounds, the most typical pectoriloquy may in exceptional instances be heard when there is no large cavity within the thorax. Thus pectoriloquy no longer carries the exaggerated importance which Laennec attached to it; indeed, one modern writer, Guttmann, omits it altogether, and includes all degrees of increased vocal resonance under the term bronchophony.

An attempt has of late been made to confine the term pectoriloquy to the sound of the whispering voice. It has long been known that an increase in the vocal resonance is often better appreciated when the patient whispers than when he speaks aloud.†

* "En me livrant à des recherches comparatives relativement à la résonnance de la voix chez plusieurs sujets sains et malades, je fus frappé par un phénomène tout-à-fait singulier. . . . . Lorsque, tenant le cylindre appliqué au dessous de la partie moyenne de la clavicule droite, je faisais parler la malade, sa voix semblait sortir directement de la poitrine et passer tout entière par le canal central du cylindre. Ce phénomène n'avait lieu que dans une étendue d'environ un pouce carré. Dans aucun autre point de la poitrine on ne trouvait rien de semblable" ('De l'auscultation Médiate,' tom. i, § 22).

† Dr Bristowe proposes by bronchophony to understand that tones generated in the larynx—by pectoriloquy that the articulate sounds formed in the cavity of the mouth—are conveyed downwards to the stethoscope with abnormal distinctness. According to this way of using the terms, when the patient speaks aloud, and when the words he utters are clearly perceived by the auscultator, both bronchophony and pectoriloquy are heard at the same time. Dr Bristowe's proposal has the advantage of introducing a real distinction into the meanings of the two terms in question, whereas hitherto the difference has been only one of degree. But its adoption would render useless, except to those who kept themselves well informed of changes in the sense of words, all the literature of the subject during the last sixty years. Moreover, it is not suggested that transmission downwards of the whisper enables any conclusion as to the state of the lung to be drawn which cannot be drawn from ordinary bronchophony. The practical importance of whispered bronchophony lies in the fact that its presence is so easily recognised, and is thus a valuable sign when there is difficulty in detecting increased resonance in the ordinary voice.

The answer to the question *why* bronchophony and pectoriloquy should be heard when the lung is solid and not when it retains its spongy structure, involves also the explanation of bronchial breathing, of consonating râles, and of the loud transmission of the cardiac sounds to distant parts of the chest. The complete physical explanation has not yet been given,* but the differences in the sounds under discussion are readily appreciable by everyone who takes the trouble needful to educate his ear; they mutually check and confirm one another; and long experience has given us confidence in assigning to them a diagnostic significance on which we can depend.

One modification of vocal resonance was named *ægophony* by Laennec, on account of its resemblance to the bleating of a goat.† It will be discussed under pleuritic effusion, of which it is a sign. Its physical explanation has been thus stated by Dr Stone.

In a course of experiments with a pitch-pipe placed between the lips of various patients and made to utter a musical note by their drawing a deep inspiration, he found that when the spoken voice, or even the whisper, yielded marked ægophony to a stethoscope placed over the affected part of the chest, there was no transmission of the sound of the pitch-pipe. Moreover, if the patient could be made to sing or to intone a good musical note, no ægophony was to be heard. Among spoken words a difference was found according to the vowel sounds they contain. The French A yielded hardly any ægophony; it was more marked with the E, still more so with the I, and most of all with U. Now, as is well known, Helmholtz showed that the different vowel sounds are formed by the addition of certain harmonic overtones in varying degrees of intensity to a fundamental tone which may be the same for all of them. And according to Dr Stone the cause of ægophony is that the fundamental tone is intercepted in its passage through a layer of pleural exudation, while the overtones are allowed to pass and, being heard by themselves, give the peculiar character to the sound. In some further experiments he succeeded in imitating ægophony. This was effected by transmitting the voice through a wide india-rubber tube, over which was placed a bladder containing water.

* Laennec was content to assume that spongy lung was a bad conductor of sound. Skoda, as the result of experiments on the dead tissues, declared the conductivity of hepatised lung to be *less* than that of the healthy organ; but he could not reproduce the conditions under which auscultation is practised during life, and it is difficult to believe that a homogeneous material does not convey sound better than a series of spaces containing air. Thus almost all recent writers reject Skoda's conclusion. He maintained that *consonance* is the cause of bronchial breathing and bronchophony. In acoustics, however, consonance has been understood to mean a power of vibrating in unison with some particular tone, or of producing sounds in harmonic relation to it. And in his work on the subject Skoda does not really limit his application of the term to consonance in a strict sense. He alludes to the effect of the sounding-board of a violin, and to the increased sound produced by a tuning-fork when it is placed upon a table. But these are examples of what writers on acoustics have termed "resonance" rather than of "consonance." In Tyndall's 'Lectures on Sound' nothing is said about consonance.

† "*De l'égophonie ou de la pectoriloquie chevrotante.*—La voix plus aiguë, plus aigre que celle du malade, et en quelque sorte *argentine*, produit seulement une illusion telle qu'il semble que quelqu'un parle dans la poitrine du malade. Elle a, d'ailleurs, un caractère constant d'où j'ai cru devoir tirer le nom du phénomène; elle est en quelque sorte tremblotante et saccadée comme celle d'une chèvre, et son timbre se rapproche également de celui de la voix du même animal. Ce caractère ne présente que des variétés légères dont on peut se faire une idée exacte en se rappelant l'effet que produit un jeton placé entre les dents et les lèvres d'un homme qui parle, celui de la voix transmise à travers un roseau fêlé, ou le bredouillement nasal des bateleurs qui font parler le fameux personnage de tréteaux connu sous le nom de *polichinelle*" ('Ausc. Méd.,' tom. i, § 154).

When a stethoscope was applied to the upper surface of the bladder an ægophonic twang became exceedingly distinct.*

PALPATION.—By applying the hand to the chest we are able to compare the extent of movement in respiration of the two sides and of the upper and lower parts of the same side. This use of the sense of touch corrects or confirms the observations of the eye.

Moreover, when the hand is placed upon the bare chest of a healthy man a tremulous sensation is felt when he speaks, especially if the voice is powerful and low in pitch. The sensation is more "voluminous" (because felt over a large space), but in quality closely resembles that of the *frémissement cataire* to be described as a sign of cardiac disease. In a woman or a child it is often not to be perceived, and on the right side it is almost always more distinct than on the left.

This normal sensation is known as tactile vibration of the voice, or *vocal fremitus*. It is increased when the lung is solidified, and is diminished or abolished when the lung is separated by liquid from the thoracic walls. In other words, it is increased under the same conditions as vocal resonance on auscultation, and diminished or absent when the vocal resonance and respiratory sounds are rendered feeble or entirely lost. In estimating tactile vocal fremitus the whole hand should be laid flat on the patient's chest, and he should be directed to speak loudly, slowly, and in as deep a tone as the compass of his voice will allow. As with other physical signs of the chest, comparison of the two sides is invaluable for bringing out the diminution or exaggeration of tactile vibration.

The practical importance of loss of tactile vibration seems to have been first pointed out in the 'Journal Hebdomadaire' for 1829 by the French physician, Raynaud, who also discovered pleuritic fremitus.

INSPECTION.—A rough estimate of the shape, size, and movements of the chest is naturally made when one first glances at the patient after he has stripped. But accurate observations are often postponed until after one has listened to the breathing over different parts of the lungs.

It is, however, better, as a rule, when a complete examination is to be made, to begin by carefully inspecting the thorax as the patient sits upright and in as easy a posture as may be before the physician. The light should be made to fall first full, and then obliquely on the chest. The shoulders should be covered by a shawl while the front is examined. The number of respirations in a minute should be counted, their rhythm, and especially the length of expiration and the degree of pause between expansion and contraction noted, and the relative movements of the chest and abdomen (denoting the predominance of thoracic or phrenic respiration) should be observed. Next the chest should be looked at in front, behind, laterally,

* Dr Stone's theory of ægophony seems to me to be fully established. And it is of the more interest because it brings into complete accord with the auscultatory phenomenon another physical sign, which (so far as I am aware) had never been thought of in connection with it, but which has long been known to be one of the chief indications of pleuritic effusion, namely, loss of tactile vibration. When the pleura contains fluid the fundamental tone, according to Dr Stone, is intercepted; and this is the one which would be felt under normal circumstances, whereas the overtones consist of waves too rapid to be perceptible to the touch. I am not sure, however, that loss of tactile vibration is to be detected in every case when the voice has an ægophonic character.—C. H. F.

When the effusion in the pleura is large, tactile vibration is absent, and also ægophony; the harmonic overtones, as well as the fundamental tone, of the voice are both cut off.

and by looking down upon it from above the patient's head as he sits, in order to measure its relative dimensions, and to compare the movements of the two sides.

Bulging or flattening of one of the infra-clavicular regions is more easily detected by standing behind the patient while he is sitting, so as to look downwards over his shoulders. A general enlargement of one side is often easily appreciable by the eye. But one must make quite sure that the patient is sitting or standing perfectly upright, especially if the case is that of a child or of a young woman with a thin flexible spine. In infants one may grasp the chest with the two hands from behind, placing the thumbs tip to tip upon one of the vertebræ. In adults a measuring tape is often used.

But, as Dr Gee remarks, circumferential measurements are apt to be fallacious, because considerable increase in the sectional area of one side of the chest may leave the length of the periphery unaltered, by "the passage of the elliptical form into the circular." It is this which renders his *cyrtometer* so useful an instrument.* It is made of two long pieces of very narrow metal gas-tubing, of an eighth of an inch in diameter, which are fastened together by a short piece of caoutchouc tube slipped over their ends. The central caoutchouc piece is placed over the spinous process of a vertebra, and the hollow metal rods are then carefully bent round the patient's body, so as to meet over the sternum. It is now easy to remove them without altering their shape; and by laying them upon a sheet of paper one can obtain an accurate tracing, which shows exactly the configuration of the two sides of the chest, and enables them to be compared. One must not forget that the half-circumference of the chest on the right side is in many healthy persons greater than that on the left side, the difference being sometimes as much as an inch.

Various instruments, called *stethometers*, for the measurement of the movements of the chest have been devised by Gibson (1848), Quain (1858), and other physicians. One of the best was Dr Arthur Ransome's, of which a description may be found in the 'Medico-Chirurgical Transactions' for 1873. But although they have yielded information as to the exact degree of impairment of mobility of different parts of the chest wall in various diseases, it seems doubtful whether any one of them has been employed in actual practice by other observers than their inventors, the reason being that they are troublesome to use, and that they bring to light no facts that may not be ascertained without them.

A similar remark applies to the exact mensuration of the several diameters of the chest carried out by means of calipers, with a graduated quadrant, devised by Woillez, Wintrich, and other physicians.

Nor does it appear that in clinical practice any results worth speaking of can be attained by the use of an instrument invented by Dr John Hutchinson many years ago for the purpose of measuring the amount of air that can be expelled from the chest by the fullest possible expiration. This instrument, which is called the *spirometer*, may possibly be of value in examining recruits for the army, or "lives" for insurance. But there are great practical difficulties in obtaining correct results; very few persons succeed in "blowing" their full amount of air into the instrument until they have had some practice.

Common symptoms.—There are certain symptoms which belong to most

* Somewhat similar cyrtometers were invented by Woillez and by Björnström, and are much used in France and Germany.

diseases of the Chest, and which are most conveniently treated of in general here. They are Dyspnœa, Cough, and Pain.

DYSPNŒA.—The use of this term is commonly limited to cases in which a sensation of "shortness of breath" is experienced, with more or less discomfort or distress. But it is better to follow the physiological use of the term, and to understand by it that the respiratory movements are deeper than natural, or more frequent, or both deeper and more frequent, without regard to whether the patient is conscious of the disturbance.

It is a remarkable fact that persons affected with extensive disease of the lungs, provided that such disease develops itself gradually, may continue to breathe as slowly as in health, and with no more effort, so long as they are at rest. The amount of oxygen supplied to the blood is no doubt much reduced; but it suffices for the wants of the system. It might have been supposed that the oxydising processes of the tissues would be checked; that sugar would be likely to appear in the urine, and that the excretion of urea would be diminished, and that of less perfectly oxidised bodies, as uric acid, be increased. But a series of experiments on animals recorded by Senator in 'Virchow's Archiv' for 1868 appears to show that this is not the case; and his conclusions are quite in accordance with clinical experience. The body adjusts its requirements to its necessities. One reason why persons affected with chronic bronchitis or other pulmonary disease almost always grow thin is that they instinctively learn to take very little food. But a far more important method of adjustment seems to be the avoidance of all bodily effort. So soon as such a patient begins to walk, especially on rising ground, dyspnœa sets in. Muscular exertion at once involves a demand for more oxygen than is contained in his arterial blood. So, again, the supervention of pyrexia in a case of this kind necessarily leads to a disproportionate increase in the rapidity and in the depth of the breathing. In illustration of this principle Cohnheim instances the remarkable subsidence of dyspnœa which often occurs immediately after the crisis in acute pneumonia, before the affected lung has even begun to recover itself.

Sometimes, however, dyspnœa of a very marked kind arises without reason to suppose that the oxidation of the blood is at all defective. This is the case, for example, in *diabetic coma:* and a distressing shortness of breath may be the earliest symptom of which the patient is conscious in the course of chronic *Bright's disease.* Of this a striking instance once came under the author's notice. He was seeing his out-patients, when the attendant nurse asked him to listen to her chest, because her breathing had become so difficult and laboured that she felt unfit for any exertion. After the most careful investigation, nothing amiss with either the lungs or the heart could be detected. Then, as she said she was thirsty, her urine was examined for sugar, and the result being still negative, it was tested with nitric acid, which brought down a large quantity of albumen. A few months later dropsy set in, and her case soon ended fatally.

Another form of dyspnœa, independent of any disease of the thoracic organs, is of *nervous* origin. It is often ascribed to hysteria; but, like other hysterical symptoms, it is not always accompanied by other signs of that disease.

Phrenic dyspnœa.—There is a peculiar form of dyspnœa which depends upon *paralysis of the diaphragm.* Its characters were first recognised by

Duchenne, and they deserve careful study, because its origin is very likely to be overlooked. So long as the patient is at rest his breathing is perfectly easy. But the slightest effort at once begins to distress him and to increase the frequency of his respirations; when he walks he experiences a sense of suffocation as soon as he has made a few steps; in mounting a staircase, and even in speaking, he is obliged to stop every instant to take breath. When he sighs he feels as though the abdominal organs were being drawn up into his chest. The act of defæcation is much embarrassed. His voice is weak; there is more or less difficulty in coughing and sneezing, because he cannot take the deep full inspiration which is a necessary preliminary; so that even a slight attack of bronchitis is attended with great danger. If one looks at the surface of his body while he breathes, the characteristic indication of paralysis of the diaphragm is generally at once apparent. During inspiration, when the ribs rise and the chest expands, the epigastrium and the hypochondriac regions are drawn in; during expiration they are pushed forwards. In other words, their relation to the thoracic movements is exactly the reverse of what it normally should be. Sometimes it is not so easy to see the alteration as to feel it with the two hands placed just below the cartilages of the ribs. If only one side of the diaphragm is paralysed, as is sometimes the case, the corresponding hypochondrium may be drawn in while the other one protrudes in the natural manner.

Among the examples of this affection recorded by Duchenne, there are some in which it appeared at an advanced stage of progressive muscular atrophy, others in which it was associated with paralysis of many other muscles as the result of lead-poisoning, and one in which it was hysterical. Walshe says that he has seen it in a well-marked form as a sequel of diphtheria. Erb cites Oppolzer as having observed it at the age of puberty without any cause being discoverable. Another cause, which is mentioned by Duchenne on the authority of Aran, is the extension of inflammation from the peritoneum or from the pleura. And he gives a case of empyema in which the muscular tissue of the corresponding side of the diaphragm was of an orange-yellow colour, and in which the fibres microscopically had undergone complete fatty degeneration.

It appears hazardous to diagnose paralysis of the diaphragm in every case of thoracic disease in which one or both of the hypochondriac regions are drawn in during the act of inspiration. That is no infrequent occurrence in a great variety of circumstances, and is often due to a mere inaction of the muscle, which surely ought to be distinguished from paralysis. The application of electricity seems not to be likely to help in clearing up the difficulty, for in all cases in which the diaphragm has been observed to be paralysed it appears to have retained its power of responding to faradic stimulation of the phrenic nerves. The best method of stimulating these nerves is, according to Duchenne, as follows:—by two fingers, placed just outside the edge of one sterno-mastoid muscle, the skin is first drawn slightly inwards; they are then separated, leaving between them an interval, upon which a small conical metal rheophore is pressed, so as to be just over the spot where the phrenic nerve lies upon the scalenus anticus. The rheophore is now given to an assistant to hold, and the same procedure is repeated on the opposite side of the neck. When both rheophores are fixed the operator takes one in each hand. He passes through them an interrupted current, which should instantly give rise to a contraction of the diaphragm, shown by the abdominal walls being pushed forwards, while

the lower ribs are separated from one another. Sometimes, however, the platysma interferes with this result, contracting with such force as to jerk the rheophores out of position. And sometimes it is necessary to shift them a little from spot to spot before one can succeed in acting on the phrenic nerves. Erb recommends a different method; he places one pole upon the neck, and the other over the attachment of the diaphragm to the costal cartilages.

Whatever position may be adopted for the rheophores, the stimulus should be so used that the resulting contraction of the diaphragm may fall in with the natural respiratory movements. The current should be stopped as soon as the muscle has acted, and a few seconds after it should be re-applied.

This procedure seems to possess considerable therapeutical value. By means of it Duchenne succeeded in completely restoring the functions of the diaphragm in a man named Bonnard, who had advanced progressive atrophy of other muscles, but in whom the paralysis of the muscle in question was as yet recent and incomplete, as was shown by the hypochondriac regions receding only when he breathed deeply. After a few weeks of treatment he became able to ascend stairs, and to walk long distances without discomfort.

Orthopnœa.—There is a kind of dyspnœa in which there is no distress and little acceleration of the breath so long as the patient is either standing or sitting up in bed; but so soon as he lies down difficulty in breathing is apparent.* That the diaphragm descends more freely when the weight of the liver and other viscera draws away from it, and that both sides of the chest act better when the weight of the body does not hamper them, either on one side or behind, is readily understood. It is as natural as the increase of dyspnœa which follows movement, and particularly ascent of rising ground. But it is not easy to explain why the advantage of an upright position is so much more marked in cases of cardiac dyspnœa than in those of bronchitis, or phthisis, or anæmia. As a clinical fact, however, while some degree of orthopnœa accompanies short breath from whatever cause, the marked form in which a patient sitting up in bed is able to converse easily, but is quite unable to lie down, and can only sleep propped up with pillows or in an arm-chair—this typical orthopnœa—is rarely seen except in cases of organic disease of the heart. It may sometimes be observed in emphysematous patients, and as a mere complication of dyspnœa it is seen in spasmodic asthma, in ascites and renal dropsy, in grave anæmia, in advanced phthisis, and in cases of pleural effusion and of pneumothorax.

Cheyne-Stokes respiration.—This is the title given by German writers to a curious variety of dyspnœa first noticed by Dr John Cheyne, of Dublin; and afterwards described by Professor Stokes, who regarded it as a symptom of fatty degeneration of the heart. An attack usually, but not always, begins with dyspnœa; this is followed by a gradual slackening of the respiratory movements until they fail altogether, and a complete pause ensues for half a minute or even longer. This condition of apnœa is succeeded by slow and shallow breathing, which gradually quickens and deepens until it resumes its former character. The whole process is of variable length, and is usually repeated several times within a few hours;

* "Ægri recto corpore residere cupiunt, qui habitus est ad eam rem aptissimus." 'Aretæi de causis et signis acutorum morborum,' lib. ii, cap. 1.

often it recurs during several days or even for weeks and months. The total interruption of the breath gradually led up to, and in like manner gradually recovered from, is the essence of the phenomenon. Its physiology has been much discussed by Traube, Schiff, Filehne, Luciani, and Wertheimer.* It may be observed in rabbits and other animals after considerable hæmorrhage; and is seen clinically not only under the condition described by Stokes, but in cases of apoplexy, meningitis, and cerebral tumours, in the uræmic state, and in the *coma vigil* of extreme anæmia and of exhaustion from fevers. It may occur during chloroform narcosis, or as a result of frequent administration of morphia. It often comes on while the patient is asleep or comatose, but sometimes when he is in possession of his faculties, walking about, and fully sensible of the peculiarity of his breathing. The pupils become contracted during the height of the fit, as in other conditions of apnœa, but this is not constant; the pulse is quickened in the ingravescent stage as the number of respirations is increased, and subsides with them, until the pause follows, when it becomes slow and incompressible.

There is little doubt that the immediate cause of this curious phenomenon is some change (probably due to anæmia) in the respiration-centre of the bulb. It is seldom or never observed in uncomplicated diseases of the heart or lungs, and rarely accompanies marked orthopnœa or severe dyspnœa. It is a symptom of nervous origin, and probably connected with deficiency in oxyhæmoglobin of the blood supplying the medulla oblongata. Its relation to fatty degeneration of the heart is perhaps rather that both are results of anæmia than that a feeble circulation causes it, for it is very rare in cases of cardiac failure from valvular disease.

As a prognostic symptom Cheyne-Stokes breathing is very grave. Undoubted cases of recovery after it has appeared have been recorded, but as a rule it only comes on in the last stages of cerebral disease, of anæmia, uræmia, or cholæmia, and points to exhaustion of the nervous centres and to approaching death.

COUGH, as is well known, is produced in the following manner:—A deep inspiration is first taken, the glottis is then closed, and, a sudden expiratory effort being made, the glottis is allowed to open, causing a loud sound, and allowing a blast of air to pass out, which may carry with it any secretion or other substance present in the air-passages. In describing laryngeal diseases we have already seen how they may modify the characters of cough, giving it a hoarse, or rough, or metallic quality, or rendering it almost noiseless. But an ordinary cough may almost be taken as an indication that the larynx is healthy.

The nervous mechanism by which cough is effected is reflex in its action. As a rule, the irritation which gives rise to it starts from the respiratory mucous membrane, as is evidenced by the consequent expulsion of mucus or pus in greater or less quantity. But sometimes the most violent and repeated efforts of coughing bring away nothing. The cough is then said to be *dry;* and in the last century the distinction between a "dry" and a "humid" cough seems to have been regarded as one of the most fundamental points in regard to chest complaints. It is, however, quite possible for the air-passages to contain mucus which is too viscid and too firmly adherent to be expectorated; and probably what is still more frequent is

* See also Dr Samuel West's remarkable case ('Lancet,' 1890, p. 545), and one related by Dr J. D. Mann ('Brain,' 1890, p. 178), which he observed for fourteen months.

that some part of the respiratory mucous membrane is affected with slight catarrh, and that this condition either itself constitutes an "irritation" or else renders the surface sensitive to the passage of air over it, or to the disturbance produced by the laryngeal movements in breathing or speaking. But, on the other hand, there is no doubt that the starting-point of cough is sometimes altogether outside the air-passages, and, as may well be supposed, the recognition of this fact is of great importance in medical practice. The question has been worked out in experiments upon animals by several physiologists, one of whom was Kohts, of Strasburg, whose observations appeared in 'Virchow's Archiv' for 1874. In regard to cough, as to all other reflex phenomena, although positive experimental results are of great clinical value, negative results prove very little. For under morbid conditions afferent nerves may transmit impressions with more than usual energy, or reflex centres may be unduly excitable, so as to be stimulated by impressions which normally should not disturb them.

The following appear to be the chief ætiological varieties of cough which have to be recognised, apart from affections of the respiratory organs.

1. *Throat cough.*—Kohts found, both in animals and in man, that irritation of the pharynx had the effect of producing cough in many individuals, but not in all. There is therefore no theoretical difficulty in admitting that catarrh of the fauces may be attended with cough, without there being a corresponding affection of the larynx; but the parts being continuous it must always be difficult, if not impossible, to say that this is actually the case, especially as Kohts showed that the glosso- and arytæno-epiglottic folds and the lateral edges of the epiglottis were among the most sensitive structures of all, so far as the production of cough is concerned. It is a somewhat different question whether a relaxed and elongated uvula frequently gives rise to cough by coming into contact with the parts behind the base of the tongue. Mackenzie speaks of this as giving rise to a "distressing tickling cough continuing all day," and some surgeons have adopted the practice of snipping off the uvula whenever a patient has complained of such a cough, for which no other cause could be discovered. But while this treatment sometimes succeeds (as, for instance, in cases recorded by Dr Garrett, of Hastings, in the 'Lancet' for 1872), its failures are at least as frequent.

2. *Ear cough.*—That cough can be excited by irritation of the external auditory meatus had been known long ago, but it was generally forgotten until Dr Cornelius Fox drew attention to it in the 'Lancet' for 1867. He examined a number of persons, and found that this peculiarity existed in about one among every five or six. He mentions the case of a gentleman who experienced a feeling of irritation of the larynx and had a violent suffocating cough whenever he introduced a toothpick into the left ear; in him, too, a somewhat similar action was capable of being exerted in the reverse direction, for long-continued singing would cause him pain in the ear. Dr Fox shows that the ear may sometimes be the starting-point of a cough under such circumstances that the relation may be overlooked. Thus a healthy-looking woman, aged fifty, had for eighteen months had a most distressing cough. As she was deaf in the right ear the meatus was examined, and was found to contain a hard plug of cerumen, and to have a small ulcer in its floor. Almost immediate relief to the cough followed extraction of the wax and the application of nitrate of silver to heal the ulcer. In a patient of Mr Toynbee's a cough was cured by the removal of a piece of necrosed bone from the external ear. It is obvious that a foreign body,

such as a bead, might have a similar effect. Dr Fox is no doubt right in maintaining that the afferent nerve in all such cases is the auriculo-temporal branch of the fifth, and not (as had been suggested) the minute auricular twig of the vagus.

3. *Tooth cough.*—Dr Fox incidentally mentions that it is well known to dentists that the stump of a tooth may be the starting-point of a cough, and he also refers to cough in infants during the first dentition as ceasing when the gum lancet is used. In investigating an obscure case, therefore, one must not fail to examine the teeth.

4. *Stomach cough.*—In the last century it was a favourite dogma that dry cough, and even humid cough, are very often produced by disorder of the digestive organs. The most recent exposition of such a view is to be found in 'Copland's Dictionary.' But, as so often happens in like cases, what has long since ceased to be taught by the faculty has become an article of faith among the public. Thus mothers still commonly refer to the stomach coughs in their children which are really due to catarrh of the upper air-passages. Or, committing a fatal error, they set down to the same cause the dry cough of early phthisis, attended (as it often is) with nausea and loss of appetite and pain in the side. It has been stated that the sign of a cough due to gastric irritation is either that it comes on when the stomach is loaded with a full meal, and disappears after the completion of digestion, or else that it occurs chiefly when the patient is in bed at night. The second of these criteria corresponds well with the fact that persons in whom intermission of the pulse and palpitation of the heart are caused by irritation of the stomach experience these symptoms when they lie down more than when they are sitting or standing. Kohts, however, in his experiments, failed altogether to excite cough by irritating the stomach. He cites from 'Brücke's Physiology' a case in which a boy coughed day and night with the utmost violence and obstinacy until he vomited, whereupon the cough at once ceased; but he adds that Brücke, who himself made the observation, believed the starting-point of the affection to have been, after all, something in the air-passages, which became dislodged when the stomach expelled its contents. Another instance, quoted from Professor Leyden, is that of a patient who had repeated attacks of biliary colic, and who every time became affected with dry cough and with pain in the right hypochondrium twenty-four hours before the jaundice set in. Walshe says that he has known the trifling irritation due to the presence of an *Ascaris lumbricoides* keep up reflex cough for several weeks.

5. *Centric cough.*—Kohts found that he could sometimes excite cough in animals by mechanical or electrical stimulation of the floor of the fourth ventricle, and he thinks that the centre for this reflex act is situated rather above that for respiration. In hysteria, as is well known, a hard, dry, barking cough is common, and this may be supposed to be centric in its origin. A remarkable instance of this was recorded by Dr John Harley in the 'Med. Times and Gazette' for 1863. The patient, a girl aged fourteen, uttered a short bark seventy times a minute without intermission, so that, according to calculation, she must have coughed 40,000 or 50,000 times in the course of the day. She had had the cough a fortnight when she came under observation. She was treated with valerianate of zinc and with a cold douche and frictions to the spine, and in three days the cough ceased. A very similar case, in a child aged eight, was described by Dr Whytt more than a century ago under the name of nervous cough. A

remarkable feature in each of these cases was that the cough ceased instantly when the patient lay down. Dr Whytt made an elaborate series of investigations into the effects of posture upon his patient, finding (for example) that the cough did not return when she sat up in bed so long as the feet were extended straight out, but that as soon as they were inclined at an angle she began to cough. He also observed that putting the feet in hot water at once arrested the cough.

PAIN is a symptom of various thoracic diseases, but it may also occur in the same places when it is the sole indication that anything is the matter with the patient, and when therefore it can only be regarded as a substantive affection.

Sometimes, perhaps, the seat to which pain is referred is the interior of the lung itself. Walshe speaks of "pains deeply felt within the chest, and shooting in the direction of the pulmonary branches of the vagi and sympathetic," as existing "independently of any other deviation from health not only local but general." He also refers to "various anomalous and more or less painful sensations, felt deeply within the chest by phthisical patients."

But in the large majority of cases thoracic pain is referred to the chest walls, and especially to one or both of the infra-mammary or infra-axillary regions. Various names are given to pain in these situations, according to the views held with regard to its nature.* The term "pain in the side," *pleurodynia*, is the best of these.

It is sometimes difficult to determine whether a pain in the side is due to pleurisy, anæmia, mitral disease, or gastric disturbance. The stomach seems to be frequently its starting-point when it is on the left side, which is the case in most instances of pleurodynia. The same is true of the pleurodynia of cardiac disease and of chlorosis. Another frequent cause is ovarian irritation, especially in women who are hysterical. The spine, too, must be thought of, even when the pain is unilateral; and we must remember that a pain in the side, if recent, may be the precursor of an attack of shingles.

Again, it is necessary to bear in mind the possible presence of disease or injury of a rib. In July, 1877, the author was consulted by a lady, the wife of an old schoolfellow, who told him that, having had a cough all the previous winter, she had one night felt something crack in her left side while she was coughing. Ever since then she had suffered from a continuous gnawing pain there. On examining the side there was considerable enlargement of one of the lower ribs, which seemed to be clearly the callus of a fracture. Under suitable treatment she got well, but for as long as six months afterwards she still experienced some pain in coughing, which, however, was no longer limited to one spot, and extended as high as the shoulder. She also said that she sometimes felt pain in the side towards

* Walshe describes in succession three separate affections, which he terms "pleurodynia," "thoracic myalgia," and "intercostal neuralgia." The distinctions which he would draw between them seem to be chiefly in reference to the intensity and duration of the pain, to its being accompanied by superficial tenderness, and to the presence or the absence of the "points douloureux" of Valleix (cf. p. 385). He limits the term *pleurodynia* to attacks of pain of extreme severity, generally setting in suddenly and lasting only a short time. Of it he says first that it is "an actual rheumatism of the walls of the chest, affecting their muscular and fibrous textures;" and then, a little further on, that "nerve-fibres are implicated, and that rheumatic neuralgia of the intercostal nerves forms an element of it." Is it not clear that the distinction is only arbitrary, and the hypothesis of rheumatism equally so?

night when she was fatigued, and that changes of weather seemed to increase it. Probably such fracture of a rib in coughing is extremely rare. In a lecture reported in the 'Lancet' for 1882, Mr Marshall relates the case of a woman, aged thirty-five, who in the severe weather of the spring of 1881 caught cold, shivered, and was attacked first with pain in the left side and then, a month later, no less severely in the right. In the previous year she had had acute rheumatism, and her case was regarded as neuralgic. At length she came to Mr Marshall, who found two firm oblong swellings, one along the lower border of the right fifth rib, and the other at a corresponding spot upon the eighth rib. When they were pressed upon she experienced acute pains shooting through to her back. They gradually softened into abscesses and were opened, when parts of each rib were found to be eroded and softened. Ultimately some pieces of dead bone came away, and she did perfectly well. In another instance, also recorded by Mr Marshall, an abscess, evidently connected with disease of a rib, arose in a patient who had phthisis. Syphilitic periostitis is another affection that must be borne in mind, although it is much less common in the case of the ribs than of the sternum. Mr Marshall speaks of it as almost confined to women.

BRONCHITIS

" Forte si tussire occæperit, ne sic tussiat,
Ut cuiquam linguam in tussiendo proferat."
PLAUTUS, 'Asinaria,' iv, 1.

General symptoms: cough, dyspnœa, pain—Physical signs: rhonchus, sibilus, râles—Morbid anatomy.
Acute Bronchitis—Capillary form—Its symptoms and prognosis—Pulmonary collapse—Its production and relation to pneumonia.
Chronic Bronchitis—Varieties—Sequelæ—Emphysema—Its anatomy and origin—Atrophic emphysema—Symptoms and signs of emphysema—Bronchiectasis, uniform and saccular—Fœtid bronchitis—Ætiology, prognosis, and treatment of bronchitis generally.
Plastic bronchitis—Its rarity—Anatomy, course, and symptoms—Treatment.

THE disease which is termed bronchitis is very common in our climate, and the word is now familiar, but it does not appear in medical literature before the publication of works in 1812 by Peter Frank in Germany, and in 1814 by Badham in England. Up to that time the disease was known as "catarrh," or "defluxion on the breast," while the more severe forms were designated by the cumbrous name of "peripneumonia notha," invented by Sydenham. Bronchitis is generally understood to include inflammations of all parts of the air-passages below the larynx. When the windpipe is very obviously affected, the term tracheitis may be used; but, as might be expected, the boundary lines recognised by the anatomist find no application in clinical practice. In a large number of cases the morbid action reaches to a greater or less extent above the bifurcation of the trachea, yet we need not speak of the disease as anything more than bronchitis.

Bronchitis as the term is usually applied refers to *catarrhal* inflammation, and does not imply either plastic exudation or ulceration.

There are few affections of which there are so many varieties as of bronchitis; and these differ, both in symptoms and in course. The most convenient plan will be to enumerate such of the symptoms and physical signs as belong to all alike, and afterwards to give separate accounts of the more important varieties.

Common symptoms.—Foremost among the general symptoms is *cough*. This is never absent, and it is often exceedingly severe, and of a loud, barking, or ringing character. It may consist of isolated explosions, succeeding one another more or less regularly, and sometimes with extreme frequency. Or it may occur in paroxysms, which sometimes end in retching or actual vomiting. It may be worse when the patient lies down, or it may come on especially when he first gets up in the morning, being excited by an accumulation of mucus or pus in the air-passages during the

night. Sometimes the irritation which sets it up is definitely referred to some one spot along the course of the trachea, which is felt to be raw or tender; sometimes there is a vague tickling sensation, which cannot be localised. The characters of the sputum differ so widely in different forms of bronchitis that it is useless to speak of them generally.

Another symptom in all severe cases of bronchitis is *dyspnœa*. It depends, in the main, upon the mechanical obstruction to the entrance of air into the pulmonary vesicles, which has its seat in the small tubes.

A curious circumstance, to which Riegel seems to have first drawn attention, is that in all affections of the bronchioles the dyspnœa is expiratory rather than inspiratory. Sometimes the act of inspiration is quite short and easy, while that of expiration is difficult and much prolonged; sometimes they are both embarrassed; but inspiration appears never to be alone impeded in bronchitis, as it so often is in affections of the larynx or trachea. This special tendency to expiratory dyspnœa, when the smaller air-tubes are inflamed, perhaps depends on paresis of the muscular fibres of the bronchia.

Another peculiarity of the breathing, which may often be noticed in children, is that each expiration is instantly followed by an inspiration, the pause in the act of breathing taking place at the end of each inspiration and not at the end of expiration, as it does normally.

In severe cases there may be *orthopnœa*, so that the patient must be propped up with pillows all night, but this is usually an indication that there is emphysema beside bronchitis.

When dyspnœa is considerable there is more or less lividity or *cyanosis*. This shows itself in the face and hands. In extreme cases the face becomes turgid, flushed, and bloated. The veins of the neck are dilated and throb with each pulsation of the right ventricle, and the superficial veins generally are fuller than natural. This condition of venous congestion contrasts with the pallor which usually accompanies the dyspnœa of phthisis, of diphtheria, of cardiac, and of renal disease.

Pain is by no means constantly present in bronchitis. Many patients, however, complain of a sore feeling behind the sternum, or in the upper part of the chest on either side. Or, again, the harassing cough may give rise to more or less severe myalgia in some part of the thoracic walls. Not infrequently this muscular pain is felt at the epigastrium. But another cause of epigastric pain is fulness of the liver, from obstruction to the venous circulation.

Physical signs.—The signs of bronchitis are less numerous than those of almost any other disease of the respiratory organs. They are mainly auscultatory, for the percussion-sound is quite unaltered unless the case is complicated with pleural effusion or with some affection of the pulmonary tissue such as emphysema, or collapse, or broncho-pneumonia.

The vesicular murmur is more or less altered in character, or is replaced by adventitious sounds. In some cases, and those not the least grave, the change in the vesicular murmur is that it is *faint* and *indistinct*; it may be absent occasionally over a part of the lung, from the corresponding bronchial tube being plugged by mucus. In this case one can usually bring it back by making the patient cough vigorously two or three times.

As a rule in bronchitis the inspiratory murmur becomes *rough* and *hard* in quality, and the expiration may be accompanied by a very similar sound. It is then sometimes difficult to distinguish this from bronchial breathing.

That, however, has a more blowing character; and it is strictly limited to certain parts of the chest, whereas in bronchitis the sound is heard over both lungs alike and very widely; moreover bronchial breathing, except over the sternum and between the scapulæ, is accompanied by more or less dulness on percussion. It cannot be too strongly impressed on those who are learning the use of the stethoscope that neither bronchial breathing nor any of its modifications occurs in bronchitis except when some complication is present. Nor is the vocal resonance in any way altered.

The adventitious sounds which occur in bronchitis are those that have been already discussed, under the names of "rhonchus," "sibilus," and "râles." *Rhonchus* (or "sonorous rhonchus") is a loud snoring or cooing noise, often audible by the patient himself and by those about him, and due to vibrations that can be felt by the hand placed upon the surface of his chest. It is formed in the larger tubes, and in bronchitis its cause is the presence of a mass of viscid mucus partly obstructing the entrance of air, and producing a *veine fluide*. The proof of this is that it can very generally be made to disappear, at least for a time, by the patient's coughing once or twice, and, indeed, it comes and goes of its own accord, being heard first in one part of the chest and then in another, as mucus happens to accumulate in different branches of the bronchial tree.

Sibilus (or "sibilant rhonchus," as some prefer to term it) is a high-pitched whistling sound. It is formed in the bronchioles, and is of much graver import than rhonchus, since inflammation of the smaller air-passages is far more dangerous than that of the larger. It seems to be due to the narrowing of the calibre of the affected tubes which results from swelling of their lining membrane. Consequently, it cannot be got rid of by coughing, and it usually remains in the same spot for hours or days together.

Many terms have been employed to denote the particular quality of these continuous "dry sounds." Sometimes they resemble "snoring," as the term *rhonchus* would imply, sometimes the hoarse "cooing" of a wood-pigeon; often they are high-pitched and musical like a box of pipes, sometimes deep in tone, like the notes of certain stops of the organ, and sometimes "wheezing," "squeaking," or "whistling."

The *râles* which accompany bronchitis may be of every variety of size. They are not of "consonating" quality, inasmuch as the lung-tissue round the tubes in which they are formed still remains spongy. If râles are not universally distributed through the lungs, they are, as a rule, most marked over the lower lobes, and behind rather than in front. Signs that might suggest the presence of bronchitis in the upper lobes only—especially if limited to the upper lobe on one side—should always arouse a strong suspicion of phthisis. A point which is worthy of mention is that it is sometimes impossible to detect any râles in cases in which the profuse expectoration would certainly have led one to expect them—only dry sounds are audible.

Diagnosis.—The symptoms and physical signs above enumerated are not sufficient in themselves to justify a diagnosis of bronchitis. It is necessary to add certain negative points by which the presence of other affections of the air-passages or of the lungs is excluded. Particularly in cases of which the clinical history is such as to render it possible that the pulmonary parenchyma may contain scattered tubercles, whether of acute or of chronic

development, great caution must be exercised in forming an opinion. Sometimes, but very rarely, the occurrence of secondary nodules of a malignant new growth in the lungs offers another chance of error. The difficulty is not so much in saying that bronchitis is present as in determining whether it is the principal affection, or only a complication. For it is exceedingly apt to arise in the course of a great variety of diseases, as measles, enteric fever, rickets, phthisis, organic lesions of the heart, and Bright's disease.

Morbid anatomy.—In mucous membranes, as in the skin, the morbid appearances produced by inflammation are far less conspicuous after death than during life; and a reason why this is pre-eminently the case with the bronchial mucous membrane is afforded by the abundance of elastic fibres in its structure. It is sometimes far from easy to determine the presence of bronchitis at an autopsy, even when it was the sole disease. A good method of detecting puriform secretion in the smaller tubes is to slice off the edge of the lung, and then to press the tissue towards the cut surface, when a yellow bead appears at each little orifice. But in many cases there is extreme redness and swelling of the mucous membrane, which may have a velvety appearance, while every part of the air-passages, up to the trachea, may be full of a yellow or brownish opaque fluid.

The histological changes in bronchitis have been in recent times particularly studied by Socoleff ('Virchow's Archiv,' vol. lxix), and by Dr Hamilton ('Practitioner,' 1879). The former examined artificial bronchitis in dogs and in rabbits produced by insufflation of bichromate of potass or of a weak solution of chromic acid; the latter studied cases that presented themselves in the *post-mortem* room of the Edinburgh Royal Infirmary. Both observers are agreed that a very early change is the detachment of the ciliated epithelium, which seems to be thrown off in flakes, and which remains absent during the whole course of the disease, to be regenerated when recovery takes place. In a young man who died of opium-poisoning, in from ten to sixteen hours, the ciliated cells were already to a great extent shed, although Dr Hamilton speaks of the morbid process in that case as having been rather acute congestion than actual inflammation. He says that the cells themselves undergo fatty degeneration, which probably destroys many of them. Others, no doubt, are expectorated; others are inhaled into the smaller air-tubes, where they may be seen lying in large detached masses among the other catarrhal products. There is an obvious analogy between this exfoliation of the columnar layer of the bronchial epithelium and desquamation of the cuticle when inflammation affects the skin. During the further progress of the attack the basement membrane is covered only by a layer of flat cells, from which there project here and there pyriform or oval corpuscles, of transitional character, which are covered by a more or less abundant mass of leucocytes, embedded in a mucoid fluid. A point on which Dr Hamilton lays great stress is that the basement membrane itself becomes thickened and swollen, apparently as the result of œdema. Both he and Socoleff are convinced that the leucocytes which appear in such large numbers upon the free surface of the mucous membrane are not derived by emigration from the blood-vessels, but are formed by germination from the flat cells that lie immediately in contact with the basement membrane. Socoleff's chief reason for maintaining this opinion was that in animals killed twenty-four hours after the commencement of the morbid process he found leucocytes on the free surface of the mucous membrane, although its

substance was at that time entirely free from them. Dr Hamilton insists especially on the difficulty which leucocytes derived from the blood would have in traversing the thickened basement membrane, and on the fact that in his preparations he could discover no indication that this was taking place. But it is perhaps worthy of notice that Socoleff himself figures ciliated epithelial cells having in their interior red blood-discs, which must have made their way through. And one naturally hesitates to accept observations upon deep-seated tissues as overthrowing the results of investigations made upon the cornea and other superficial structures, for the special purpose of determining the nature of the inflammatory process (cf. p. 45).

In all but very early and very slight cases of bronchitis the mucous or submucous tissues are, in their whole substance, more or less thickly filled with leucocytes, which are collected in lines along the lymph spaces between the fibrous bundles and around the vessels. Dr Hamilton is satisfied that these also are in great part derived by germination from the flat endothelial cells of the lymph spaces or from connective-tissue corpuscles. Another very important change occurs in the mucous glands. They become swollen so as to be sometimes as large as hemp-seeds, according to Riegel. Their epithelium undergoes very active proliferation, and the newly-formed cells become distended with mucin, and appear to be the source of the mucus that often forms so large a part of the expectoration. This mucus, however, becomes mixed with leucocytes and epithelial cells of "transitional" form, as well as with saliva and air-bubbles.

When bronchitis has existed for a great length of time before death the changes found *post mortem* are somewhat different. The mucous membrane is often pale and grey, with but few vessels visible. In many cases it presents a number of delicate longitudinal ridges, which Rindfleisch has shown to consist of an overgrowth of connective tissue, containing very numerous cells, and bundles of elastic fibres running in various directions. According to Dr Hamilton the muscular coat is sometimes found to be hypertrophied, sometimes atrophied. The cartilages shrink and disappear, undergoing the same change which occurs in articular cartilage, namely, the absorption of the matrix from the periphery inwards, with the formation of "medullary spaces" filled with leucocytes. In many cases the mucous glands also are destroyed. At an earlier period their orifices are widely dilated, giving the mucous membrane a minutely pitted appearance when looked at with a good light; and sometimes they become inflamed, forming minute funnel-shaped ulcers.

Of the various forms of bronchitis some run an *acute*, others a *chronic* course.

ACUTE BRONCHITIS.—This often affects mainly the larger air-passages, so that it may fairly be called a "tracheo-bronchitis;" and in such cases the inflammation is sometimes derived by extension from the nose and throat. The cough is often very distressing, and especially violent when the patient attempts to lie down. He may complain greatly of a sore sensation along the sternum; and pressure upon the trachea may be painful and may at once excite cough. This form of the disease, however, is not dangerous.

Capillary form.—Very different is the course of acute bronchitis when it attacks the bronchioles throughout the lungs, for this may be one of the

most rapidly fatal of all diseases. It is distinguished as "Capillary Bronchitis," which answers to what was formerly called "Suffocative Catarrh."

It usually sets in with a sensation of chilliness, or less frequently with a rigor which may be repeated. The degree of pyrexia varies; the temperature may range up to 104°, especially in children; more often it is at a lower level; and it does not run any typical course. The head and the upper part of the body become covered with sweat. The hands and the surface generally feel hot and the face is more or less flushed. The pulse is frequent, sometimes so rapid that it cannot be counted. It is often tense and full, perhaps as the result of contraction of the systemic arterioles.

But the most prominent symptom of this form of bronchitis is the dyspnœa. The patient sits up, with chest heaving and with nostrils quivering, unable to utter more than two or three words at a time, using his shoulders and arms in violent efforts to breathe. On carefully inspecting the thoracic movements, one finds that there is a great obstacle to the entrance of air into the lungs. The epigastric and the hypochondriac regions of the abdomen recede at every inspiration; in children all the lower ribs and lower part of the sternum may be forcibly sucked in. The supra-clavicular and the suprasternal spaces also recede, but, on the other hand, as Seitz has pointed out, the upper ribs often remain almost motionless in a position which is that of a forced inspiration, giving to the corresponding part of the chest a vaulted shape.

The cough of capillary bronchitis is often exceedingly harrassing. At first it is usually dry, there being nothing in the air-passages to be expectorated. Afterwards it is accompanied by more or less abundant sputum. The secretion of the inflamed bronchial mucous membrane, goes through stages very similar to those that may be observed during the progress of a cold in the head. It begins by being swollen and dry, then it pours out a transparent mucous fluid; after a time this becomes mucopurulent, and finally almost pure pus. These changes are what the older medical writers described as "concoction." The dry stage sometimes lasts several days, or even throughout the whole duration of the disease. Thus Dr Latham in his 'Lectures on Subjects connected with Clinical Medicine,' narrates the case of a boy, seven or eight years old, who for six days remained in a condition of extreme suffering, with shrill sibilus audible all over his chest, and then gradually recovered without expectorating anything. A point, however, which must not be forgotten is that infants and children as old as this patient commonly swallow whatever they cough out of the air-passages into the mouth. In older patients, when sputum first appears, it is as a rule scanty and dislodged with great difficulty, the patient perhaps coughing a number of times in rapid succession, until he is purple in the face, before he can get relief by bringing up a translucent pellet of mucus. But in other cases the spitting-jar becomes filled in a few hours with a considerable quantity of a greyish-white glairy liquid, which has numerous air-bubbles entangled in it. Under the microscope this kind of sputum is found to contain remarkably few formed elements. As already remarked, in bronchitis the tubes cease for the time to be lined with columnar epithelium. It is therefore probable that when a few cells of that type are seen in the matters expectorated (except at the very commencement of the disease) they have been derived from healthy and not from inflamed parts of the air-passages, just as flat epithelial cells are often seen which come

from the throat or the mouth. Cells of transitional form, however, and mucous corpuscles are present in small numbers, and as the case advances pus-cells abound more and more until the sputum becomes opaque and of a greenish-yellow colour. It now comes freely, and with little effort, so that the cough is said to be "loose."

Event.—In many cases, after acute bronchitis has lasted for some time, the quantity of expectoration begins gradually to diminish from day to day; the other symptoms become less and less severe, and presently the patient recovers from his attack. But in other cases the inflammatory exudation accumulates in such large amount as to threaten death by suffocation. Râles then become audible all over the chest, and are so loud that no trace of vesicular murmur can be anywhere detected. Indeed, they are often heard at a distance from the patient. Still more important as a warning of danger is the supervention of cyanosis; the flushed cheeks, the lips, and the hands assume first a faint lilac, and finally a leaden colour; the blood is no longer duly aerated, and a condition of asphyxia has begun.

Another very grave symptom is the failure of effort on the part of the respiratory muscles; the breathing gradually becomes more and more shallow, until at last it may be represented only by a slight flickering movement of a few of the ribs, or by a faint jerking contraction of the diaphragm. With this, too, the patient ceases to be conscious of the necessity for active breathing. Instead of remaining upright he sinks down in bed, with his head in any position in which it may happen to be placed. His mind may wander for a time and then he becomes unconscious. Sometimes death is preceded by convulsions.

As a rule, if acute bronchitis is to end fatally, it does so in the course of the first fortnight, and in some rare cases the patient succumbs within twenty-four or forty-eight hours. But it not infrequently happens that when the disease has apparently been subsiding favourably, a relapse occurs which puts an end to all hope of recovery. It need not be said that the patient's muscular strength is one of the most important points that one has to take into account in attempting to form an estimate of the probable issue in a state of acute bronchitis. In very old persons the prognosis is always doubtful; it is so likewise in those who are very fat, or who are already weakened by previous illness, or who have progressive muscular atrophy affecting the shoulder or trunk muscles, or any considerable deformity of the spine or of the chest.

In infants, the chance of recovery is better in proportion to the age; while the gravity of the disease is greatly increased by the presence of rickets. We must be cautious, however, in giving an unfavourable prognosis in the case of children. It is surprising how rapid may be both the pulse and the breathing, for two or three days together, in those who ultimately recover.

Complications.—In acute bronchitis the digestive organs are often disturbed in a manner that is not readily accounted for, since the degree of pyrexia is but moderate. The tongue is often coated with a thick whitish-yellow fur. There may be nausea and vomiting, and the bowels may be obstinately constipated. In children it is sometimes difficult to say whether the abdominal or the bronchial symptoms are primary.

But the most important complications of acute bronchitis, when it attacks the smaller tubes, concern the substance of the lungs. One of them

is known as *collapse* of the pulmonary tissue; the other is an inflammatory affection known as *broncho-pneumonia*. This is distinct in its origin, pathology, and histology from true or acute pneumonia; but since, unfortunately, that term is applied to at least three separate diseases, it will be more convenient to consider it in the next chapter.

PULMONARY COLLAPSE is identical with a state of lung which is seen in infants as the result of imperfect respiration, and which is nothing else than a persistence of the fœtal condition of the tissue. That, however, is properly termed Apneumatosis or Atelectasis (ἀτελής = imperfect, ἔκτασις = expansion). It affects the whole of both lungs if the child has never breathed at all, or parts of the lungs (especially the anterior edges) if it has breathed incompletely, from having been prematurely born, or being weakly, or having its air-passages obstructed by mucous.

A German writer, Jörg, is generally credited with having been the first to point out, in the year 1832, the real nature of the atelectasis, which before was supposed to be congenital pneumonia; and it is commonly said that the patches of collapsed lung also were up to that time confounded with red hepatisation. But Bright in 1828, writing of the morbid appearance found in the lungs of two children who had died of whooping-cough, showed that he clearly recognised the difference; and Dr Alderson also is said to have drawn attention to it. The distinction between these two affections is unmistakable. A collapsed part of the lung is, indeed, reddened, and the colour of its cut surface is reddish brown, or, when covered with pleura, reddish purple or violet. A section of it, however, looks perfectly dry, smooth, and homogeneous; it has not the dull, lustreless, and granular appearance of hepatisation. Moreover, its surface lies below the level of the adjacent air-containing parts of the lung, whether seen in sections or on the pleural surface; if it reaches the free edge of the organ it forms a notch there. Lastly, inflation from the bronchus will usually restore to it its normal appearance.

Sometimes, however, collapsed pulmonary tissue is at the same time œdematous, and then its characters are less marked, its cut surface being moist and emitting serum when gently squeezed.

Collapse after bronchitis must be distinguished from the airless condition called *carnification*, which is caused by compression from pleural effusion; here the tissue is bloodless as well as airless, and the colour is slaty or mouse-coloured instead of being reddish brown.

The way in which collapse arises was well illustrated in a case which occurred at Guy's Hospital in 1874. A child, aged two years and two months, died four days after the performance of tracheotomy for a chronic laryngeal affection. Upon the under surface of the left lung there was a narrow red line of collapsed lung-tissue. This had running through it a tube which (like all the other tubes in the same part of the organ) happened to have become dilated as the result of the chronic obstruction to the child's breathing. That tube was plugged at its upper part by a piece of sponge, about a quarter of an inch long, which had evidently fallen into the trachea at the time of the operation. The limitation of the collapse to the part of the lung served by the obstructed tube was perfect. As a rule, collapse is secondary to closure of the corresponding tube by viscid mucus.

How this brings about the affection has only lately been well under-

stood. Gairdner, in 1850, suggested that the plug acted like a ball-valve, allowing air to escape during expiration, but preventing its entrance during inspiration. But the explanation always seemed unsatisfactory, and would not account for the complete disappearance of the air, inasmuch as the elastic force of the pulmonary tissue and that of the confined air must soon become inadequate to raise the valve. Lichtheim, of Berne, in an important research recorded in the 'Arch. f. exp. Path.' for 1879, showed that in rabbits collapse follows within twenty-four hours after a bronchus has been plugged by a piece of laminaria, which becomes swollen, so as to prevent passage of air in either direction. It is therefore evident that the affection must depend mainly, if not entirely, upon absorption of the air by the blood which circulates in the walls of the alveoli; and Lichtheim gives reasons for believing that the several gaseous constituents of atmosphere are taken up with different degrees of rapidity, the carbonic acid and the oxygen first, and afterwards the nitrogen. A further result of his investigations is the proof that the elasticity of the pulmonary tissue is not exhausted until it has become completely devoid of air. For without the aid of this elasticity, absorption by the blood must cease before collapse would become complete.

The state in which a lung is found when there has been slight narrowing of the space in which it lies (whether from pleural effusion or enlargement of the heart or pushing up of the diaphragm) is inexplicable, unless it be admitted that whenever even a small part of the organ fails to be acted on by the forces which are concerned in inspiration, its elasticity brings about a total collapse of its substance, notwithstanding that the tubes which serve it may be patent. This, it must be admitted, is a hard doctrine to accept; but there seems to be no doubt about its truth. Now, in bronchitis, at least in children, it often happens that large portions of the lower lobes of the lungs are unacted upon by inspiratory forces, for (as we have seen) the lower ribs and even the sternum are commonly drawn inwards, instead of rising, during the act of breathing. And the same thing occurs in croup and in other diseases attended with laryngeal obstruction. It therefore appears probable that collapse of the lower and anterior edges of the lungs, which is so often seen under such circumstances, is generally, if not always, due directly to the cessation of inspiratory traction upon those parts of the organs. And Bartels, as far back as 1860, showed by dissection that it is in fact often impossible to demonstrate any plugging of the tubes passing to collapsed areas of pulmonary tissue. So, again, we may refer the collapse of the bases of the lungs, which is so commonly seen in the bodies of those who have died of enteric fever, to the shallowness and imperfection of the respiratory movements. Even when collapse depends upon obstruction of tubes, an important factor in its production is a deficiency of power in the muscles of the thorax. For, with strong muscles, there is not only the chance that a fit of coughing may expel a plug of mucus, but also that a vigorous inspiratory effort may succeed in drawing air into the tissue in spite of it. Accordingly, in adults collapse scarcely ever occurs as the effect of primary bronchitis. Even in children its development is greatly favoured by a rachitic state of the ribs, and perhaps also by the muscular weakness resulting from measles or any other acute disease; and the younger the child the more likely is it to show collapse of the lungs under a bronchial attack.

The view that inspiratory retraction of the lower part of the chest is

generally the cause of collapse of the lungs, is not incompatible with the opinion that an extensive collapse due to obstruction of the corresponding bronchial tubes may sometimes in its turn lead to a falling in of the thoracic walls. Dr Gee, for example, describes unilateral shrinking of the chest as resulting in some cases from collapse of the whole of a lung in consequence of plugging of its main bronchus. Generally speaking, however, the space in the pleural cavity vacated by a collapsed portion of pulmonary tissue is filled up by over-distension of other parts of the organ. Moreover, if an entire lung should become emptied of air, the opposite lung undergoes enlargement and displaces the mediastinum.

Some writers believe that pneumonia is apt to arise in collapsed portions of lung tissue, in which case the anatomical distinctions between collapse and hepatisation would of course fail. Lichtheim found in his experiments that acute œdema of the affected lung sometimes occurred, so that, although airless, it was bulky, soft, and moist. The retention of secretion in obstructed tubes is suggested by Jürgensen as a probable cause of inflammatory irritation; and Lichtheim, in some instances in which an animal survived for a considerable time after obstruction of the bronchus, describes the lung as looking almost like a sacculated kidney, full of dilated channels distended with pus. But, as a rule, pulmonary tissue, when collapsed as the result of disease in the human subject, remains uninflamed. If there are patches of broncho-pneumonia in the same organ, their presence is merely a coincidence.

So far as appears, collapse, whether arising from bronchitis or from laryngeal obstruction, is always a temporary condition; for the affected parts of the lung again receive air if recovery takes place from the primary disease. The author has never seen in the *post-mortem* room any unmistakable results of collapse at a former period.

With the exception of the collapse which occurs at the extreme bases of the lungs as the result of inspiratory retraction of the chest walls, this condition, when secondary to bronchitis, seldom affects more than small portions of each organ, lobules or groups of lobules scattered here and there, some on the surface, others in the interior. Hence it does not often give rise to very definite physical signs; though, if many patches should exist in close proximity to one another, it is possible that there would be more or less dulness on percussion, deficiency of vesicular murmur, and perhaps bronchial breathing. As regards symptoms, all that can be said is that collapse aggravates the dyspnœa already produced by the bronchitis.

CHRONIC BRONCHITIS.—This, like the *acute* form, varies widely in its degree of importance and of severity in different cases. Some of its mildest forms are seen in children and in young adults, who from time to time have attacks of what is termed bronchial catarrh, until, as they get older, they perhaps ultimately "grow out" of them. Other cases, chiefly in persons advancing in age, take the form of what is called a winter cough. Year after year, during the cold season, they become troubled with a cough, which leaves them entirely in the summer, and which is attended with more or less muco-purulent expectoration. Sometimes it occurs only in the morning, when they rise from bed; sometimes it goes on at intervals throughout the day; sometimes it is very bad at night, so as to disturb their rest. For a time there is not the least dyspnœa. Gradually, however, they find that in muscular exertion, as in walking uphill, or in

mounting stairs quickly, the breath becomes short and hurried. Still it is surprising how little heed is paid to such symptoms, which, among the poorer classes, seem to be taken almost as a matter of course. In making autopsies we repeatedly find the tubes in the lower parts of the lungs filled with pus, and even dilated, and the lungs themselves markedly emphysematous, in the bodies of patients who had perhaps died in the surgical wards of the hospital, and who had never made any complaint of pulmonary symptoms. But after a few years this cough continues even during the summer; and there is constant dyspnœa, the breathing being hurried and wheezing, especially during any exertion. For a long time there is no loss of flesh; but at length wasting occurs, and it may reach an extreme degree.

It is only during the early stages of chronic bronchitis that it is possible for the patient to recover, so as to remain henceforth free from the liability to its return when exposed to cold or damp. But even in advanced cases the disorder may often be kept at bay if the patient is able to avoid changes of temperature, and to spend every winter in a warm climate, or else to remain indoors throughout that season of the year. In this way life may not infrequently be preserved to its natural term.

When death occurs, it is sometimes as the result of an intercurrent acute attack. For those who suffer from chronic bronchitis are exceedingly liable to exacerbations which always cause more or less anxiety, but which may pass off, leaving behind only increased susceptibility for the future.

In other cases chronic bronchitis ends fatally by the supervention of dropsy, exactly like that which attends primary cardiac disease. The right chambers of the heart are then dilated and hypertrophied; and the trunk and branches of the pulmonary artery are thickened, just as in cases of mitral stenosis. In one instance the wall of the pulmonary artery was actually thicker than that of the aorta, and it was also atheromatous. Such changes probably never take place until emphysema of the lungs has developed itself; and the obstruction to the pulmonary circulation is sufficiently explained by the defective aëration of the blood which occurs under such circumstances, and by the diminution of the capillary area in the pulmonary system of vessels. Traube laid stress upon a third factor, namely, the deficiency of the movements of expansion and retraction of the lungs in breathing, which under normal conditions further the flow of blood through the pulmonary capillaries. Ultimately the liver may become "myristicated," the spleen and the kidneys indurated, and the stomach congested. It is, however, remarkable how rarely these results of long and extreme venous congestion are seen in cases of chronic bronchitis with emphysema, compared with their constancy in those of mitral disease. One important element in bringing about these more remote changes is the occurrence of granular degeneration in the muscular substance of the right side of the heart. Another, which has not yet received its due share of attention, is a like degeneration of the diaphragm, as pointed out by the late Mr Callender in the 'Lancet' for 1857, and by Zahn, in vol. lxxiii of 'Virchow's Archiv.'

Certain varieties of chronic bronchitis demand separate mention. One of them is that which Laennec called *catarrhe sec.* A like form of acute bronchitis has been already mentioned. But the cases now referred to are described by Riegel as having a duration of several months, and as often

ending fatally, at least in children. The most prominent symptom is a paroxysmal cough, which is so violent that the face becomes purple and the veins of the neck swell out. Yet there is no sputum, except perhaps a little tough mucus. Pyrexia is very slight, or altogether absent.

Another variety of chronic bronchitis is attended with a remarkable flow of a thin watery albuminous liquid from the mucous membrane, so that the name of *bronchorrhœa serosa* has been given to it. Laennec relates the case of an old man of seventy, who for ten or twelve years spat up about four pints of this watery secretion every day, and yet remained not ill-nourished. But in other instances, as Andral pointed out in his 'Clinique Médicale,' extreme emaciation occurs, with weakness and pallor, almost like what might have been caused by profuse hæmorrhage.

Chronic bronchitis, if it lasts long, gives rise to certain secondary affections of the pulmonary parenchyma and of the air-passages themselves, which add greatly to its gravity. They are known as "pulmonary emphysema," and "bronchiectasis" or "dilatation of the bronchi."

EMPHYSEMA—pulmonary or vesicular emphysema—must not be confounded with that condition of the subcutaneous and other connective tissues which also bears the name of emphysema, and which depends upon infiltration with air as the result of injury to some air-containing structure. What adds to the confusion is that in the lung itself infiltration of air into the sub-pleural connective tissue does sometimes, though rarely, occur, and may go on until, passing along the root of the lung, the air diffuses itself through the mediastinum, and reaches even the superficial fascia of the neck and of the chest; this last affection is technically known as "interlobular" or "interstitial" and "sub-pleural emphysema."

A very complete description of emphysema as regards both its anatomical character and its symptoms was given by Laennec; before then it had almost escaped notice. Its real nature was first pointed out by Rokitansky, who showed that it consists in part of an over-distension of the pulmonary alveoli, but also in part of an atrophy of their walls, causing their cavities to run together into regular spaces, sometimes of very large size.

Over-distension of the alveolar tissue does not in itself justify the lung being called emphysematous. In children who have died after a few days' illness of laryngeal diphtheria, or croup, or acute bronchitis, it is common to find the lungs very bulky, and looking far more open-textured than usual. One is apt to speak of this condition as emphysema. But it is clear that there has been no time in such cases for the occurrence of atrophy of the alveolar walls, and in all probability if the patients had recovered the lungs would quickly have returned to their normal state. Even when some amount of emphysema seems to be really present, it may happen that immediately after an attack of dyspnœa a great apparent increase of the condition can be made out by physical signs, which yet subsides again within twenty-four hours. Hertz, in 'Ziemssen's Handbuch,' mentions the case of an asthmatic patient, aged thirty, in whom he observed such a transitory over-distension of the lungs on several distinct occasions.

Anatomy.—The presence of emphysema of the lungs in the dead body is recognised partly by touch and partly by sight. The substance has a peculiar soft and silky feel; it scarcely crepitates, if at all, when squeezed between the finger and thumb; and pressure upon its surface readily causes

a deep pit, which remains after the pressure is removed, proving the loss of the normal elasticity of the pulmonary tissue. Another effect of the same cause is failure of the lungs to collapse when the chest is opened. They often remain fully distended, and the left lung covers the heart, so that scarcely anything is to be seen of that organ. In a case which was observed at Guy's Hospital in 1868, one lung overlapped the other behind the sternum by an inch and a quarter. A similar condition, which must have been pathological, was found in a body which the writer, when demonstrator of anatomy, froze for the purpose of making a transverse section; a wax model of that preparation, which is now in the museum, shows one lung covering the other for some little distance; there was advanced phthisis, and it is very likely that emphysema also existed, although this was not proved to be the case. In extreme instances the lungs bulge in all directions, both during life and after death, displacing the structures around them. Their apices protrude far above the clavicles; and their bases bulge so that the diaphragm instead of being arched upwards is flattened. In two cases the pericardial sac was pouched inwards at its lower part, so that Dr Moxon described the heart as resting upon and as being separated from the surface of the diaphragm by cushions of lung.

Sometimes there are large bullæ or blebs containing air, of all sizes up to that of a walnut or a pigeon's egg. These are seen chiefly along the anterior borders of the lungs, but sometimes also along their inferior borders or near their roots. Not infrequently the ear-shaped process of the left lung shows a more marked degree of emphysema than any other part. But in some instances, even when the lungs are very highly emphysematous, no large cavities are to be seen.

The tissue if closely inspected is found to be full of spaces of the size of small shot or of millet-seeds. One noticeable appearance is a rounding off of the free edges of the lungs, and their outer surfaces often show marks of the ribs, the intercostal spaces having yielded so as to allow the lungs to bulge outwards. Emphysematous lungs are of a grey colour, mottled with spots and lines of pigment; they are soft and inelastic, but not friable, and their cut surface is dry and bloodless.

The earliest change in a lung that is becoming emphysematous is, according to Rindfleisch, a dilatation of the infundibular cavities into which the alveoli open; according to Hertz, a nearly uniform dilatation of the infundibula, and also of the alveoli themselves. Gradually the alveolar walls waste, until nothing is left of them but small ridges projecting a little way into the interior of an oval or rounded space, into which each infundibular cavity and its alveoli have now become resolved. After a time the septa between these spaces in their turn thin away and become perforated. Thus the result is a progressive increase in the size of the spaces with a diminution of their number. An aggregation of fatty granules round the remains of the nuclei of the alveolar epithelium is commonly present; and in the 'Med.-Chir. Transactions' for 1848 Mr Rainey maintained that the morbid process concerned in emphysema is primarily and essentially a fatty degeneration; but there is no reason to suppose that this is the case. There is, of course, an enormous destruction of capillaries when the affection is at all extensive. Rindfleisch speaks of the vessels as collapsing until "only a narrow ribbon-like band is left, which may be recognised as an obliterated vessel by its greater transparency amid a dark, often pigmented, parenchyma, and by its uniting with other bands like

itself to form the usual anastomotic network." He goes on to say that relatively wide communications are opened up between the pulmonary artery and the pulmonary and bronchial veins. These anastomoses appear in well-injected lungs as peculiar elongated unbranched channels of the same diameter throughout, strikingly contrasting with the far more numerous, extremely tortuous, and dilated arteries, for the contents of which no such supplemental mode of escape has been provided.

Pathogeny.—With regard to the mode of origin of emphysema of the lungs there have been many different opinions.

Laennec's idea was that the tubes in cases of bronchial catarrh being obstructed by swelling, or by an accumulation of mucus, the air which found its way into the alveoli during inspiration became unable to escape during expiration, inasmuch as the expiratory force was less than the inspiratory. In other words, he thought that emphysema was the result of a process the exact converse of the ball-valve action which, as we have seen, was supposed by Gairdner to be the cause of collapse. Louis objected that the ordinary seat of catarrh is the base and lower part of the lung, whereas the parts most apt to be affected by emphysema are the apex and the anterior margin.

In 1851 Gairdner advanced the theory that emphysema arises solely during inspiration. His view was that collapse or reduction in bulk in one part of a lung is a necessary antecedent to the development of emphysema in another part. During inspiration, when the chest becomes enlarged, if each and all of the lobules cannot expand to fill it, some of them must be stretched unduly; and this produces emphysema.

For a few years Gairdner's view was widely accepted, and emphysema was held to be essentially "complementary" or "compensatory" either to collapse, or to retrogressive tubercular disease, or to some other contracting lesion of the lung. But in 1856 Sir William (then Dr) Jenner addressed to the Royal Medical and Chirurgical Society a powerful argument, in proof that the development of emphysema occurred during expiration. And it is now known that this same doctrine had already been taught in Germany, as far back as 1845, by Mendelssohn, in a work entitled 'Der Mechanismus der Respiration und Circulation.' Gairdner urged that it is impossible for emphysema to be produced by the act of expiration, even with a closed glottis, because the force by which the air becomes compressed within the lung opposes exactly as much resistance without as it creates pressure within. Jenner now pointed out (as Mendelssohn had done before) that certain parts of the thoracic walls are yielding, and consequently incapable of maintaining this resistance. Both these observers indicated the apices of the lungs as being devoid of adequate protection against an expanding force from within; and we have seen that Louis had long before shown that the apices were especially apt to become emphysematous. Jenner remarked that during a fit of coughing the supra-clavicular regions may be seen to bulge, and that by placing one's hand upon them one can feel that they are distended by a considerable force. If the apices are the seat of emphysema this bulging under violent expiration is extreme, and percussion over the bulging parts may elicit an almost tympanitic sound. He further showed that the upper costal cartilages are to some extent yielding, and that therefore the alveoli of the anterior margin of each lung become affected with emphysema as well as those of the apex. Other parts which he also named as apt to become emphysematous were—

the margin of the base of the lung, the part of the lung near its root below the entrance of the bronchus, and the little ridge of lung which, on the right side, projects behind the trachea. The base of the left lung generally he showed to be less firmly supported than that of the right, the liver being more unyielding than the stomach; and he cites Louis as having found the left lower lobe emphysematous twice as often as the right one.

The correctness of Jenner's theory has since been supported by observations made in certain cases of congenital malformation of the chest walls. Thus in the case of Groux, who had a fissure of the sternum, the anterior part of the lung protruded through the fissure in the act of coughing. Ziemssen met with an example of absence of the *pectoralis minor*, and of the entire sterno-costal part of the *pectoralis major*, so that the intercostal muscles of the four upper spaces were covered only by fascia and by integument. During forced expiration these spaces bulged from 1 to 1½ mm. above the level of the ribs; when the muscles of one space were faradised that space for the time remained flat, the others bulging as before. Further evidence is afforded by cases in which, after the cicatrisation of penetrating wounds of the chest, the affected parts have ultimately become the seat of hernia of the lung, as the result of weakening of the thoracic parietes. Many such instances may be found collected in a little work published by Desfosses in 1875. It may be noted, too, that horses are liable to an affection of the lungs identical with emphysema, as the result of the straining efforts which they are called on to make, during which they keep the glottis closed. As Sir William Jenner says, in vol. iv of 'Reynolds' System,' "no one who watches a horse draw a heavy load up a short steep incline on a damp cold day can doubt this. While making the effort the horse holds its breath, having previously inflated the lungs. No sooner, however, does this animal cease its effort than the glottis is opened, and the air suddenly expressed from the lungs. The degree to which the air was compressed may be judged by the distance to which, and the sudden violence with which, the cloud of breath-vapours is seen to be driven forth." In his paper in the 'Med.-Chir. Transactions' Jenner had shown that the parts of the lungs that are emphysematous in a "broken-winded" horse are those which are so placed as to be least able to resist pressure. It is curious that a capital description of this affection of horses was given before the end of the seventeenth century by Sir John Floyer, in a treatise on asthma; the passage is cited in full in 'Watson's Lectures.'

Emphysema, then, is the result of expiratory pressure with a closed, or partially closed, glottis. The expiratory muscles forcibly compress the air within the chest, and if all parts of the thoracic parietes were equally unyielding no harm would result. But as certain parts can and do yield, some of the compressed air is driven into the corresponding alveoli of the lungs, and gradually breaks down their structure in the manner already described. No doubt the resistance of the chest walls in different regions fails progressively, more and more, as the affection advances. Thus the sternum and the upper cartilages become arched forwards, a change which probably is due to the frequently repeated application of an expansile force from within the thorax. It is only as the result of long-continued pressure that the diaphragm can become flattened, and that the lung can protrude inwards beneath the heart, as described above.

Even when a part of the lung (generally the apex) is shrunken by retrogressive tubercular disease, most pathologists now agree with Jenner in

thinking that the development of emphysema in the tissue around, particularly along the anterior edges, is due to the pressure of air driven into the alveoli by coughing. Others, however, still hold that to such cases Gairdner's theory remains applicable, and that the emphysema is "complementary" in the strict sense of the term.

Although a frequently repeated cough is one of the chief causes of emphysema, yet in man, as in horses, other actions beside coughing may increase the expiratory pressure so as to produce the same result. This is the case, for example, with all violent efforts in which the glottis is kept closed to fix the chest. Dragging or lifting heavy weights, straining at stool, even the act of parturition, may be mentioned as possible causes of emphysema. Thus Waldenburg is cited by Hertz as having seen the affection develop itself in a medical student who, having come from a country place where he had no occasion to ascend the stairs, occupied in Berlin an apartment on the fourth floor, up to which he ran without stopping several times daily. Hertz himself met with a similar case in a young shopman, whose lungs became emphysematous in about a year, without any cough or bronchial catarrh, as the result of his having to carry heavy goods up a high staircase in haste a great many times every day. For persons who have suffered from bronchitis, and in whom the distending process has already begun, it is most important to avoid all occupations or amusements that involve repeated expiratory efforts. Playing a wind instrument may sometimes be exceedingly injurious; for, although the glottis is not closed, the air within the chest is kept under great pressure, while it is being slowly allowed to escape.

Atrophic emphysema.—Of late, German observers have been disposed to attribute emphysema in part to primary changes in the pulmonary tissue independent of the mechanical conditions just described. A *senile atrophy of the lungs*, bearing a close resemblance in its characters to emphysema, is generally admitted by pathologists; it was originally described by Dechambre in 1835, from observations made at the Salpêtrière. Sir William Jenner speaks of it as "*small-lunged emphysema*," in contrast with the ordinary form of the disease, which he calls "large-lunged emphysema." As he says, the small size of such lungs, their lightness, and the very small space into which they may be compressed, are often most remarkable. When the thorax is opened after death they "fall in like an inflated bag of wet paper." The subjects of senile atrophy of the lungs are commonly thin, shrivelled, and withered-looking. Their chests are very small and narrow, the lower ribs being so obliquely placed that they almost reach the crest of the ilium, and so closely packed as nearly to come in contact with one another. The lungs are so reduced in size that the extent of præcordial dulness may be increased, notwithstanding that the heart partakes of the general wasting. Yet there is commonly little distress of breathing, because the volume of the blood is at a minimum, and because the deficiency of muscular power forbids active exercise.

It has always, however, seemed to the author that the supposed likeness of this senile atrophy of the lungs to emphysema is really due to the fact that a slight degree of emphysema resulting from the bronchial catarrh to which aged persons are so liable is commonly mixed up with it. Hertz, in his chapter on atrophy of the lungs in 'Ziemssen's Handbuch,' speaks of bronchitis as a frequent "complication;" and he also mentions that the bronchioles are very thin and "generally uniformly dilated, seldom irregularly sacculated." But brochiectasis can hardly be otherwise than mechanical

in its origin; and it seems reasonable to take the same view of the pulmonary rarefaction, which Hertz describes as being most marked at the apices and along the anterior edges.

Predisposition.—That in younger persons some cause for emphysema must exist, beyond expiratory pressure upon the alveoli, is argued by Hertz from the fact that in certain families several members are found to suffer in succession, as the result of comparatively trifling affections of the air-passages. Schnitzler, for example, saw three brothers, whose parents were still alive and well, but who all became the subjects of emphysema at the age of thirty, without definite cause. Walshe cites Dr Jackson, of Boston, as having upheld the view that the disease is transmitted by inheritance; he found that "of twenty-eight emphysematous persons, eighteen had either a father or a mother, or both, similarly affected; whereas of fifty non-emphysematous people, three only sprang from emphysematous parents." Dr Greenhow once argued for a relation between emphysema and the "gouty diathesis."

So far as concerns the mere occurrence of this affection in different members of the same family, it is important not to overlook the fact that they may all have been alike exposed to the causes of bronchial catarrh, and perhaps all alike unduly susceptible of taking cold. But Cohnheim and other recent German writers have looked for an explanation of emphysema, apart from mechanical causes, in a varying physical state of the pulmonary tissue, as regards its degree of elasticity. In this connection certain observations of Perls may be cited of which there is a record in vol. vi of the 'Deutsches Archiv.' By means of a pressure gauge he determined in a large number of cases the degree of force with which the lungs retracted when the pleural cavities were opened in the dead body; and he found that after death from enteric fever, or (in one case) from phosphorus-poisoning, their elasticity was reduced almost to nothing. Cohnheim regards it as an established fact that in a very large proportion of cases emphysema depends upon a congenital defect of development in the elastic tissue of the lungs. But the reference which he gives to a paper by Eppinger in the 'Prag. Vierteljahreschrift' for 1876 does not seem to bear out this assertion; for although Eppinger found that even in slightly emphysematous lungs there was a great reduction of the network of elastic fibres in the alveoli, the smallest fibres having completely disappeared, he yet appears to have regarded this as a change occurring in the course of the development of the disease, and not as an antecedent malformation.

In this connection a case recorded by Hertz is of great interest. It is that of a regimental cornet-player, aged thirty, who had always been able to use his instrument without any difficulty, even on the march. He was attacked with double pneumonia, which, however, subsided in a week; he felt quite well, had no cough, and began again to practise with his cornet. But in the course of the next seven months he discovered that he was no longer able to take sufficient air into his lungs to maintain a long note for the proper period, that he was short-breathed on exertion, and could no longer play while marching. Hertz found on examination that the lungs were markedly emphysematous, which had not formerly been the case; and his supposition is that the pneumonia had damaged their texture, so that they were not able to resist expiratory pressure as before.

Clinical symptoms.—The recognition of emphysema is based mainly upon physical signs. The chief subjective symptom of the disease is *dyspnœa*. The patient first notices that he is short of breath when he exerts himself,

as in running upstairs; but after a time difficulty of respiration becomes a permanent condition from which he is never entirely free. As Dr Walshe says, he feels as if his chest were never emptied of air as it naturally should be; and he is conscious of an annoying sense of inflation or distension. It is true that many emphysematous persons affirm that their dyspnœa is only occasional; but Dr Walshe says that in all such cases which he has seen, the patient has been deceived, a moderate amount of dyspnœa having become to him a second nature—a thing unperceived and giving rise to no discomfort.

It does not necessarily happen that the affection advances; it may continue stationary, and life may be maintained until extreme old age, provided that the risk of intercurrent attacks of bronchitis can be obviated. Hertz supposes that the existence of emphysema necessarily involves an increased liability to bronchial catarrh, by leading to congestion of the mucous membrane of the air-tubes; but it would be difficult to prove this, seeing how very common bronchitis is as an antecedent condition.

On the other hand, in the majority of cases emphysema becomes more and more marked every year. After a time the noisy hurried breathing may become so short that the patient cannot utter a sentence without stopping in the middle of it. At night he has to be propped up by pillows. His distress becomes aggravated from time to time, sometimes by an exacerbation of bronchial catarrh, sometimes by the supervention of asthma, sometimes by mere pushing upwards of the diaphragm, as the result of distension of the abdomen with flatus, or with undigested food. The face, the hands, and at last the whole body become livid, as if from capillary bronchitis. In fact, chronic bronchitis never goes on for any length of time without being complicated with more or less of emphysema, so that it is impossible to separate the effects of each. Cough, on the other hand, may be entirely absent in cases of emphysema unless there is bronchial catarrh. But many persons, whose main disease is emphysema, constantly have cough, and expectorate a frothy liquid, or pearly-grey masses of mucus.

Hæmoptysis is not generally counted among the symptoms of this affection. Sir Dyce Duckworth, however, in the 11th volume of the 'St Bartholomew's Hospital Reports,' declares that it is of not infrequent occurrence. In 1869, a woman, aged forty-nine, was brought dead into Guy's Hospital after an attack of severe hæmoptysis, and at the autopsy the only disease that could be discovered was an extreme degree of emphysema of the upper lobes of the lungs, with some excess of fibrous tissue forming the interlobular septa. The air-tubes were full of clots. She was said to have suffered for three months from wheezing and short breath; on the morning of her death she woke up at 4.25 a.m. with "coughing and vomiting of blood through the nose and the mouth, and was suffocated in ten minutes."

Ultimately emphysema gives rise to great wasting, and to extreme enfeeblement of the muscular strength. A noteworthy circumstance, mentioned by Walshe, is that the over-distension of the chest renders the body unnaturally buoyant in water, so that the patient is astonished to find himself able to swim more easily than before, at the very time when he is growing more and more incapable of other kinds of exertion.

Physical signs.—Of these the most important are derived from *percussion*. Even very slight degrees of emphysema may be detected by carefully mapping out the areas of the heart and of the liver. Instead of beginning

at the upper border of the fourth left costal cartilage, the cardiac dulness begins only over the fifth or even the sixth cartilage. Instead of beginning at the upper border of the sixth right rib, the hepatic dulness begins only at the level of the seventh or of the eighth. If in a case of bronchitis one finds that percussion over these two organs yields normal results, one is generally safe in declaring that no appreciable amount of emphysema has yet developed itself.

As the disease advances, the heart becomes so completely covered by the lungs that no cardiac dulness at all can be detected, the pulmonary resonance above meeting the tympanitic note of the stomach below. At the same time the apex-beat ceases to be felt in the normal position, in consequence of the downward displacement of the diaphragm carrying the heart with it; and the cardiac pulsations can often be felt in the epigastrium. On the right side pulmonary resonance now extends down to the margin of the thorax. The edge of the liver may sometimes be felt in the hypochondrium. But very often this is not the case, and there may be a marked reduction in the area of the hepatic dulness, so that one may be tempted to suspect that the organ is atrophied or cirrhosed when this is not really the case. This seems to be due to the great increase in the antero-posterior diameter of the thorax preventing the liver from coming in contact with the parietes of the chest and abdomen to the normal extent. Another noticeable feature of well-marked cases of emphysema is the clear character of the percussion-sound over the sternum as high as its upper border; and over the bases of the lungs behind a clear percussion-sound is elicited to a much lower level than normal.

Moreover the percussion-sound, over parts of the chest where it ought naturally to be resonant, is over-resonant, and according to Walshe and Gee there is often a fall in its pitch. The change in the percussion-sound is often very conspicuous over the back of the lungs, a sonorous drum-like note being readily produced where normally there is often difficulty in eliciting a clear resonant sound.

Next to percussion, *inspection* affords the most valuable indications of emphysema. As already explained, the sternum and the upper ribs arch forwards as the result of their yielding to the frequently repeated expiratory pressure which is the cause of the affection. The sternum not infrequently becomes convex in a vertical plane, with an angle, known as the *angulus Ludovici*, at the junction of the manubrium with the body. The clavicles also are more bent than under normal circumstances. The curve of the dorsal vertebræ becomes greatly increased, so that the back is rounded. The effect of all these alterations in the parietes of the chest is to give it a cylindrical form. It is often aptly said to be "barrel-shaped." By the cyrtometer its horizontal circumference is shown to be almost perfectly circular, as is well illustrated in a diagram given by Dr Gee. Sometimes the rounding of the ribs and of their cartilages continues to the very bottom of the thorax, and the hypochondriac regions are permanently expanded to the fullest possible extent. One result of this is, as Hertz has pointed out, a transverse groove, which crosses the abdomen horizontally from one twelfth rib to the other; it is due to the stretching of the upper part of the transversalis abdominis muscle, which is fixed to the rib cartilages, as compared with the relaxed condition of the lower part, which has no such attachment. This groove may form a conspicuous, and at first sight puzzling feature of a case, when there is at the same time a considerable accumula-

tion of fluid in the peritoneal cavity. But in other instances the lower ribs and their cartilages are flattened, or even hollowed inwards; this occurs especially when the pulmonary affection began in bronchitis or whooping-cough at an early period of life, so that the bases of the lungs became collapsed.

The "subcostal" angle at the ensiform cartilage is far more open than usual, as obtuse as in deep inspiration.

The upper intercostal spaces in emphysema are either unaffected, or narrowed, while the lower ribs are widely separated. Stokes declared that he had never seen the spaces otherwise than depressed; but Walshe and others say that it is not uncommon for them to be prominent or bulging when the parts of the lungs beneath are highly emphysematous.

The high shoulders, increased depth of chest, short and full neck, raised ribs, closer together above and wide apart below, with the obtuse substernal angle, are the physiological characters of the chest during deep inspiration, and can be imitated by filling the lungs and holding the breath. The same fulness of the chest may be the result of distension of the pleura by fluid on one side or the other, but when bilateral it is characteristic of emphysema alone. It is the exact opposite of the "expiratory" form of chest seen in advanced phthisis.

Further indications as to the presence of emphysema, and as to the extent to which it is advanced, are yielded by observation of the act of breathing. During inspiration the chest in well-marked cases is seen to be almost motionless. It is, indeed, impossible for the upper ribs to rise and expand, as they normally should do, because they have permanently assumed a position in advance of what could have been reached in health. There is, however, a jerking movement upwards of the thorax as a whole, produced mainly by contractions of the sterno-mastoid and scalene muscles, which start into unnatural prominence, and appear to be hypertrophied. If the lower ribs are thrown outwards as much as the upper ones, the chief agent in inspiration must be the diaphragm. But in many cases the state of affairs is reversed. The lower ribs still retain a certain degree of mobility, but the diaphragm is pushed downwards, so that it can do little towards enlarging the thoracic cavity. It may then be observed that the epigastrium becomes hollowed during the act of inspiration.

Violent cough causes bulging of the supra-clavicular spaces; and in cases of emphysema Sir William Jenner warns against confounding this condition at the root of the neck with prominence of the same part due to distension of the veins. A still more important source of error is the sudden protrusion of an aneurysmal sac during the act of coughing. Another point to which Jenner has drawn attention is, that if one is feeling the pulse of an emphysematous patient while he coughs violently one perceives the artery to become suddenly full and tense, and it ceases for a moment afterwards to beat.

Auscultation gives comparatively little information in cases of emphysema, apart from signs of the bronchitis that is so commonly associated with it. The most marked sign of the emphysema itself that is given by the stethoscope is enfeeblement or nearly complete absence of the vesicular murmur. The bronchial breathing which may normally be heard over the roots of the lungs behind, and on the sternum, is often wanting in emphysematous patients; but even in those who are healthy this is not infrequently the case. The expiration is exceedingly prolonged owing to the

loss of elasticity in the lungs. Walshe says that, instead of being only one third the length of the inspiration, it may be four times as long; in other words, its relative duration may be increased twelvefold. The growling, squeaking, or wheezing expiratory sound of emphysema is very commonly spoken of; but it seems doubtful whether this sign does not belong rather to a concomitant bronchitis than to the pulmonary lesion itself. In one case, at Guy's Hospital, as the tubes became free, this sound entirely disappeared, although the extremely feeble state of the inspiratory murmur and the over-resonance of the percussion-sound clearly showed that emphysema still persisted.

In cases of emphysema the *vocal resonance* is much diminished, and tactile vocal *fremitus* is often entirely lost.

In the latter stages of pulmonary emphysema a tricuspid regurgitant murmur may often be detected; and even at an earlier period increased pressure in the pulmonary artery may be indicated by an accentuated second sound. Epigastric pulsation and pulsation of the veins of the neck with each beat of the heart may also be observed. These symptoms are all the result of obstruction in the pulmonary capillaries having led to dilatation of the right side of the heart and incompetence of the tricuspid valve.

When air has escaped into the subpleural connective tissue, constituting what is known as "interlobular" or "interstitial emphysema," there is sometimes heard a friction-sound very like that which occurs in pleurisy. This sign was originally noticed by Laennec. Most writers since then have been disposed to doubt the correctness of the observation; but it has been recently confirmed by Dr Gairdner; and Dr Hudson, in his edition of Stokes's works, says that he also met with a case in point.

The *treatment* of emphysema will be considered with that of bronchitis at the end of the present chapter.

Hypertrophy of the lungs.—The barrel-chest above described, *i. e.* the thorax when filled by the ordinary or "large-lunged" emphysema, is closely simulated by a condition which is physiological rather than diseased, and may be described as uniform overgrowth of the lungs. It occurs to some extent in all healthy persons who are engaged in hard manual labour or in athletic sports. The chest of the youth who improves his wind by rowing, or of the workman who is accustomed to carry heavy weights, becomes expanded, and the lungs increase in volume and capacity. When the efforts made with the glottis closed are too great, rupture of the air-vesicles is apt to occur, and thus true emphysema may be mingled with physiological hypertrophy; but this is far from a necessary complication.

Ascending ladders and climbing hills, especially when a weight is carried on the shoulders, has a similar effect. Greater efforts of inspiration are made, the lungs are expanded more perfectly, and the breathing capacity of the chest is increased.

Habitually breathing rarefied air produces similar but exaggerated effects. In persons who live in mountainous regions both causes of hypertrophy of the lungs combine; they are frequently ascending heights, often with burdens on their shoulders, and they are constantly breathing air at a low pressure, so that each cubic inch of lung gives them less oxygen to aërate their blood. The result is that the thorax becomes enlarged in all its dimensions. Instead of a yard's girth for a man of moderate stature, and a metre's

for a tall man, the chests of men of five feet six inches or even less measure more than forty inches in circumference.

This condition may be observed in Swiss guides; but it has hitherto been found most constantly and highly developed among the natives of the lofty table-lands of the Andes, in Bolivia.

DILATATION OF THE BRONCHI; BRONCHIECTASIS.—This condition was first described by Laennec. It is seldom a primary disease, and is often found associated with fibroid induration of the tissue between the enlarged tubes; such cases will best be discussed in the account of Cirrhosis of the lung. In other cases the pulmonary parenchyma is either healthy or emphysematous or collapsed: the bronchiectasis is the result, not of interstitial pneumonia, but of bronchitis.

Anatomy.—All writers divide bronchiectasis into cylindrical and sacculated, and the definition is of pathological and clinical importance.

In the *cylindrical* form the tubes sometimes run through the substance of the lung, with but little diminution of calibre, until they end abruptly beneath the pleural surface; their appearance is often compared to that of the fingers of a glove, but it rarely happens that the dilatation is so uniform throughout their whole length. In one instance, which occurred at Guy's Hospital in 1873, the bronchial tubes were so enlarged as to be conspicuous at the root of the lung, "pushing the lobes apart from one another," as it is expressed in the report of the autopsy. More often the medium-sized and smaller tubes are alone affected. The existence of bronchial dilatation may then be obvious on the cut surface of the lung, far too many large orifices being visible, from which pus wells up in great quantity; or, in order to detect the enlargement of the tubes, especially if they are empty, it may be necessary to open them up with scissors. Judging from the author's own observations, slight forms of bronchiectasis are much more often met with in the extreme bases than in any other parts of the lungs. Not infrequently he has seen enlargement of the principal tube passing into the ear-shaped process of the left lung when no such change could be made out elsewhere. This was when that process itself was emphysematous; and, indeed, these less-marked examples of bronchiectasis are very often found in association with emphysema. On the other hand, when the bronchial affection reaches an extreme degree, there is seldom a corresponding amount of rarefaction of the pulmonary tissue. If the tubes in any one part of the lung are universally dilated, running to the surface side by side, and perhaps as large as quill pens, or even larger, the parenchyma between them is necessarily reduced to a small space. In these cases it is sometimes difficult, at the first glance, to say whether the affection is or is not secondary to a fibroid change in the lung itself. But in the most marked and typical cases of cylindrical bronchiectasis, such as occur in children after whooping-cough or measles, the tissue between the dilated tubes is often quite free from induration or other morbid changes.

It must be understood that cylindrical bronchiectasis is by no means absolutely uniform in diameter at different points. Sometimes the tubes gradually widen as they approach the surface. Sometimes they have fibrous bands or trabeculæ projecting from their walls here and there, and rendering their calibre very irregular.

Sacculated dilatation of the bronchial tubes, also, varies widely in character in different cases. The most typical form is one which presents

appearances that have scarcely yet been exactly described. When a section is made of the lung the cut surface appears to be covered with an immense number of shallow, smooth-walled depressions, like so many minute saucers. Each of these has in its floor a very small rounded orifice, and it is obvious that they are all sections of small bronchiectases, which probably were spherical before they were cut across, but have become flattened by their own elasticity, and by that of the adjacent pulmonary tissue. In all likelihood, if the lung in such a case could be inflated and dried, and the parenchyma then cleared away so as to expose the tubes in their continuity, each would be found changed into a regular series of globular dilatations, so as fairly to deserve the epithet moniliform. In other instances sacculated bronchiectases are more unequal in size and irregular in form; but it is probable that most of such cavities are really not dilated tubes, but smooth-walled vomicæ which have been formed by ulceration. It is to these latter sacs that in all probability the statement of Biermer applies (in vol. v of 'Virchow's Handbuch'), that the majority of the sacculi of bronchiectasis have openings only towards the trachea, and are closed on the distal side. Still less are true bronchial sacs ever converted into shut cysts.

Dilated bronchial tubes often have exceedingly delicate walls, being apparently thinner than they were before they began to increase in size. But sometimes the tissues are thickened, the lining membrane being velvety and showing the changes above described as occurring in bronchitis.

Pathology.—As to the way in which bronchiectasis arises, there can be little doubt that it is the mechanical result of expiratory pressure, being in fact produced by exactly the same cause as emphysema. To explain satisfactorily why in one case the alveoli should yield, and in another case the tubes, would perhaps be impossible. But we may fairly suppose that it depends upon the degree to which the walls of the tubes have been softened by inflammation, and also, it may be, upon the amount of elastic resistance originally possessed by the lungs and bronchi in each individual. (See Dr Grainger Stewart's paper, 'Edin. Med. Journ.,' July, 1867.)

A more frequent cause of dilated bronchi is chronic interstitial pneumonia, but with this form we are not at present concerned.

Independently of previous organic changes in the lung, bronchiectasis is not frequent either in children or adults. It sometimes complicates emphysema, but more frequently takes its place.

In children it is most often a sequel of whooping-cough, and sometimes comes on very early, and so severely that the patient grows up in a state of permanent cyanosis, with cold extremities and short breath.

In adults bronchiectasis occurs in middle rather than advanced life, and is almost always preceded by bronchitis, seldom by tubercular disease, and never by acute pneumonia.

Diagnosis.—It is only when bronchiectasis has reached an extreme point that it is characterised by definite *physical signs*. As a rule, the chief indication of this affection is the presence of râles which appear to be too large and coarse to be formed in the undilated tubes of the part of the lung in which they are heard, as, for instance, at the extreme base, or along the anterior edge. If, however, a number of tubes cylindrically dilated are arranged side by side, while the lung tissue between contains but little air, there may be more or less marked bronchial breathing, bronchophony, and even dulness on percussion. But such a case could not be clinically distinguished from primary chronic pneumonia, with bronchiectasis as a result.

Again, the question of the diagnosis of a saccular dilatation of a bronchial tube from a phthisical vomica, to which stethoscopists formerly devoted themselves with much ardour, applies to the dilatation which attends cirrhosis of the lung, not to cases arising out of bronchitis alone. One circumstance which is strongly indicative of bronchiectasis is for the physical signs over a certain part of the lung to undergo more or less regular variations from time to time, being now well marked, and now again indistinct or absent.

As for its *symptoms*, dilatation of the tubes is of course in part concerned in causing cough, dyspnœa, and lividity in patients affected with it. But one can never clinically separate its share in producing these effects from that due to the bronchitis which is always associated with it, and perhaps also to concomitant emphysema. The only thing that enables one to diagnose bronchiectasis with confidence is a peculiar way of expectorating which may in some cases be observed. For some hours, perhaps, there is no cough at all. During this time liquid is accumulating in the dilated parts of the air-passages, the sensitiveness of which appears to be blunted, so that they do not resent its presence. At last perhaps some runs over into a tube which is still healthy. The result is a more or less violent fit of coughing, by which all the liquid that has collected is suddenly expelled, pouring out of the patient's mouth, and even through his nose, so as to half fill his spittoon. Sometimes this process is set in action by percussion of the chest. Sometimes it occurs, especially in the morning, when the patient rises from the recumbent posture. When this accumulation has been got rid of he usually feels much more comfortable than before, the breathing is easier, and the chest less oppressed. Such intermittent expectoration (or in children vomiting) of pus is a sure sign of dilated bronchi.

Fœtid or putrid bronchitis.—It is especially in cases in which the bronchial tubes are dilated that bronchitis becomes accompanied with the expectoration of foul-smelling sputa, and sometimes with horrible fœtor of breath. Traube has, indeed, recorded one or two cases in which putrid bronchitis occurred without there having been any bronchiectasis; but as a rule it is only when liquids have been long stagnant in some part of the air-passages, or in a space communicating with them, that putrefactive chemical changes occur.

The characteristic symptom of this rare disease, as was first pointed out by Traube, is the presence in the matters expectorated of certain soft, friable, smooth masses, of a dirty greyish-yellow colour and very fœtid odour, varying in size from a millet-seed to a bean. Such bodies had been originally noticed by Dittrich in 1850 as plugging the affected tubes in fatal cases; and in Germany they are commonly called "Dittrich's" or "Traube's plugs" (*Bronchial-pröpfe*). Microscopically they are made up of pus-cells and granules mixed with oil-globules. Later on, they also contain certain long, narrow, acicular crystals, of which Virchow gave a description long ago in the first volume of his 'Archiv,' as consisting of a fatty acid. These crystals are colourless, often sharply bent or twisted, sometimes collected together in sheaves or in thick bundles. Some of them may appear to be varicose, a condition which Traube has shown to be the result of pressure by the cover-glass. According to Guttmann they contain a combination of palmitic and stearic acids. In 1867 Leyden and Jaffé further pointed out, in vol. ii of the 'Deutsches Archiv,' that under high powers the granular detritus is composed of fungi, some round, others rod-shaped, others forming beaded chains or

filaments (*Leptothrix pulmonalis*). Their presence appears to be the reason why iodine often gives a purple or a violet, or even a blue tint to the whole mass, as Virchow and Gamgee independently observed. Chemical analysis of the sputum of putrid bronchitis, in different cases, has also shown that it may contain volatile fatty acids (valerianic and butyric acids), leucin and tyrosin, ammonia, and sulphuretted hydrogen.* It is also worthy of mention that Leyden and Jaffé succeeded in inducing in ordinary muco-purulent sputum, outside the human body, a putrefactive process closely analogous in its results to that which must be supposed to give its peculiar character to the expectoration of patients with putrid bronchitis.

In putrid bronchitis the sputum as a whole is generally very abundant. It often separates in the spittoon into three layers: of these the uppermost is muco-purulent, opaque, greenish yellow, and frothy; the middle is a transparent albuminous liquid like serum; the lowest is granular, and of a dirty yellow appearance, consisting of swollen pus-cells and their remains, together with Dittrich's plugs. Sometimes the sputum is of a uniform chocolate colour.

The odour of the patient's breath and sputum in cases of putrid bronchitis is often identical with that of gangrene of the lung. But in other cases it is of an altogether different character. There is, of course, great difficulty in defining the distinction verbally; Guttmann compares it with the smell that pervades a soap factory. Dr Laycock's statement is that in one of his patients the odour was like "that of the may-flower or of apple-blossom, with a kind of *arrière goût* of fæces." The author has often observed this kind of smell, especially when the dilated bronchial tubes were emptied with a gush of enormous quantities of fluid after the manner described above. Probably in such cases there is no active process going on in the walls of the affected tubes themselves. On the other hand, in many of those cases in which the odour is like that of gangrene of the lung the development of fœtor in the sputa indicates the abrupt commencement of a destructive change, both in the air-passages and in the pulmonary parenchyma, which rapidly brings about a fatal issue.

The credit of having first pointed out the clinical features of cases of this kind belongs to Dittrich (1850). His description is that it "commonly arises in persons of the middle period of life, who have suffered for years from bronchial catarrh, with abundant muco-purulent expectoration, and who may either have already begun to waste, or may still remain well nourished. Suddenly, and without apparent cause, the sputum becomes offensive, of a dirty grey colour; the breath also stinks, poisoning the air around. Thereupon follow severe dyspnœa, fever of typhoid character, rapid collapse, an earthy, dirty yellow complexion, and ultimately cessation of expectoration, coma, and death." At the autopsy the walls of some of the bronchial tubes are found intensely inflamed and sloughing. There are more or less extensive areas of pneumonic consolidation, passing here and there into gangrene. Other parts of the lung tissue are œdematous, exuding a fœtid liquid. The bronchial glands are swollen, soft, and of a dirty-grey colour. Several like cases were afterwards recorded by Traube.

* The authority for including methylamine and acetic acid in the list is Dr Gregory, of Edinburgh, as reported by Dr Laycock in the 'Med. Times and Gazette' for May, 1857. See, however, a valuable paper on the chemical characters of fœtid expectoration by Dr Gamgee ('Edin. Med. Journ.,' March, 1865), and one by Bamberger in the 'Würzburger med. Zeitschrift,' 1864.

The occurrence of hepatisation and gangrene of the lungs is by no means limited to those regions which were before the seats of bronchiectasis. Pneumonic patches may be scattered throughout every part of the organ on each side; and it seems obvious that many of them owe their origin to the inhalation into healthy tubes of particles of putrid *débris* derived from others which are already diseased.

But the issue of putrid bronchitis is not always thus serious. Slight cases sometimes end in recovery. We must then suppose either that there has been no ulceration of the walls of the tubes, or that the necrotic process has been limited, and that healing had taken place after detachment of sloughs of no great size. Other cases, again, run on for months with but little change in the symptoms, and without marked impairment of the general health. The general treatment is that of chronic bronchitis (p. 979). The special treatment of the fœtor is that of pulmonary gangrene (p. 1017).

To complete this account of the effects of dilatation of the bronchial tubes it must be mentioned that in vol. xv of the 'Deutsches Archiv' Gerhardt has recorded two cases in which painful swelling of some of the joints occurred as a sequela. He was inclined to regard this as analogous to gonorrhœal synovitis, or to that which sometimes follows dysentery.

The occasional supervention of abscess of the brain as a complication of suppuration in the air-passages or in the lungs has been referred to elsewhere (*supra*, p. 626).

Ætiology of bronchitis generally.—The chief cause of ordinary acute and also of chronic bronchitis is *exposure to cold*. In all probability cold air entering the air-passages through the mouth sometimes acts upon them as a direct irritant. The nasal mucous membrane warms the inspired air; but when persons venture out of doors in cold weather, with a bronchial surface already sensitive, there is often catarrh of the nasal mucous membrane which compels them to breathe through the mouth. The analogy of so many other inflammatory affections of internal structures, which contain no tubes communicating with the external atmosphere, is in favour of the view that bronchitis may also be set up by the action of cold upon the surface of the body; and this is borne out by the fact that in many cases there is no reason to suppose that cold air has been inhaled. A patient may, for example, "take a chill" by getting wet through, by sitting in a draught, by lying on damp grass, by merely remaining motionless out of doors when perspiring profusely after exertion. As a rule, it is especially when the body has been heated and is cooling that danger of catching cold exists. The reason appears to be that, whenever the body has more heat to dispose of than is required to maintain its temperature, the cutaneous capillaries become dilated to allow as much loss of heat as possible. This is equally true whether the heat is supplied to the organism from without or generated in its interior, as the result of muscular exertion. Accordingly, after a Turkish bath, one plunges for a few seconds into cold water, which causes contraction of the blood-vessels, before one ventures to sit in a room at an ordinary temperature. Rosenthal, and afterwards Riegel, have shown by direct experiment that if animals after exposure to great heat are removed and placed in air which is not warmed, they go on cooling until their temperature falls below the normal point. They therefore suggest that, when a person catches cold,

what occurs is that blood from the surface of his body, chilled by loss of its heat, is carried to deeper structures, until they also become less warm than natural. If now there be anywhere a weak spot, it suffers and becomes inflamed. In most cases probably the first effect of external cold is to set up sore throat and coryza, and then the inflammation spreads to the trachea and bronchi.

Some persons are far more sensitive to the action of cold than others. The risk of catching cold may, however, be often obviated to a great extent by "hardening" the skin, that is, by exposing it regularly to sudden changes of temperature, so as to accustom its vessels to contract promptly and vigorously. The best way of doing this is doubtless to sponge the surface with cold water, or to use a cold douche or a shower-bath every morning after a tepid bath. The cold bath by itself is probably less effectual for the particular end in view, although it is all that is required for robust persons with an active circulation, in whom it is followed by a good reaction. Even in young children a warm bath, especially in the morning, is best followed by rapid sponging with cold water.

Many *secondary* or *predisposing* causes of bronchitis are really conditions which favour the injurious action of cold. Thus the disease is very apt to attack young children on account of their feeble powers of resistance. A curious point that came out in some investigations made by Geigel as to the infant death-rate in Würzburg was that bronchitis was relatively less fatal to illegitimate than to legitimate children, the reason being in all probability that the latter are more coddled up and kept warm, so as to be rendered more sensitive to cold than if less care of them were taken.

The prevalence of bronchitis in Europe is, as might be expected, least in the hot season of the year, from June to September, and its proportionate frequency in different months is not the same as that of acute pneumonia. This is true also of the geographical distribution of the two affections. Bronchitis increases in frequency from the equator towards the poles, but the increase is not uniform in all longitudes, for it varies with the climatic conditions of each particular country. What favours it most is not a low mean temperature, but the occurrence of sudden and violent changes. In some parts of the tropics bronchitis is by no means uncommon at the end of the hot season. There are certain countries in which it is of very rare occurrence, particularly Egypt, the western prairies of North America, the plains of India, a part of the West Indies, and California.

Next to cold, the entrance of irritant substances into the air-passages during breathing is the most important cause of bronchitis. In discussing the ætiology of phthisis we shall have to consider the influence of various occupations, in which the inhalation of dust is almost inevitable, upon the production of that disease. Such occupations also cause a great liability to bronchitis, which may either in the course of time be followed by the development of phthisis, or may run a chronic course without complication until it ends fatally by the supervention of an acute attack, or by dilatation of the heart and dropsy. Pulverulent substances which happen to be coloured, such as carbon or oxide of iron, often tinge the sputum deeply when they have been inhaled. But, on the other hand, it may happen that a miner, whose lungs are black with coal-dust, spits up a yellow mucopurulent fluid, containing no carbon whatever. This accords with the fact that the bronchial mucous membrane never itself becomes the seat of anthracosis; even the peribronchial tracts of fibrous tissue derive the black

deposit which is found in them from the surrounding pulmonary alveoli, and not from the tubes themselves.

The inhalation of gases, especially nitrous or sulphurous acid, is exceedingly irritating to the air-passages, and not infrequently sets up acute bronchitis in workmen whose occupations expose them to it. But, according to Hirt, the chronic form of the disease is comparatively seldom traceable to this cause. After one or two acute attacks a tolerance seems to be established, and no further ill effects are observed. On the other hand, he speaks of the emanations from certain oil-works, from tar factories, and from the pans in which brine is evaporated to make salt, as having a beneficial influence on the bronchial mucous membrane.

The *treatment* required for bronchitis varies widely in different forms and in different stages of the disease, so that it is not easy to lay down general rules.

In the milder forms of acute *bronchial catarrh*—such as are called by some writers tracheo-bronchitis—little is necessary beyond placing the patient in an equal temperature, which should be at about 63°. Small doses of ipecacuanha, with neutral salts like nitre, are probably serviceable by favouring exudation from the inflamed mucous surface. The application of mustard plasters or of hot flannels sprinkled with turpentine to the throat and to the upper part of the chest often gives great relief to the sense of soreness along the trachea and behind the sternum. In slight cases a linseed poultice and inhaling steam are efficient and agreeable remedies.

Very different measures are necessary in cases of *capillary bronchitis*. Sometimes, if suffocation appears to be rapidly impending and the right side of the heart to be overloaded, it is advisable to bleed from the arm. Antimony is often the best medicine, and for a day or two it may be given in considerable doses, so as to produce decided nausea. Another drug which may be very successful is lobelia, the ethereal tincture of which is prescribed in half-drachm or even in drachm doses at frequent intervals. There are some patients, however, for whom all depressing remedies are obviously unsuitable. In these serious and often dangerous cases the administration of turpentine sometimes affords the best chance of arresting the fatal issue which is threatening. In one of the very worst cases which the author ever had to treat, life appeared to be saved by alternate doses of turpentine and of champagne. Ammonia in frequent doses is another most valuable drug.

It is important to maintain a moist state of the air round the patient. A kettle on the fire, with a long tube throwing steam out near the patient's bed, fulfils this indication better than anything else. But when it is used, one must never forget that the ceiling and the curtains necessarily become saturated with damp, and that if the temperature of the room should be allowed to fall a few degrees during the night, or in the early morning, a chill will result, which may probably be fatal to the patient. In some cases the inhalation of steam gives much relief, or a medicated spray may be employed, containing conium juice, or morphia, or salines such as chlorate of potass or ammonium chloride. Large poultices are commonly placed round the whole chest from front to back; and mustard or turpentine is applied until the surface is thoroughly reddened.

After a few days it is generally necessary to substitute for nauseant

drugs, like ipecacuanha or antimony, such remedies as carbonate of ammonia, squill, and senega.

In *chronic bronchitis* a great variety of medicines are useful; the difficulty is to formulate rules for selecting one rather than another. If the cough is dry and hard, ipecacuanha is most serviceable, and to this squills and nitre are often usefully added. If it is distressing by its frequency and apparent aimlessness, bromide of ammonium or of potassium often gives relief. In such circumstances morphia or opium may be taken with great advantage. The compound tincture of camphor is an excellent form to prescribe. After a few hours' sleep the patient may wake greatly refreshed, and in all respects better. It is, however, always necessary to consider, before prescribing opiates in a case of bronchitis, whether one is likely to do harm by checking cough, and so preventing the tubes being emptied of their contents. If there is lividity, stupor, or even drowsiness, such medicines must be carefully avoided. In many cases, especially if the expectoration is viscid and abundant, sal ammoniac is very useful; it may be given in doses of gr. xv to gr. xx, with a little syrup of lemon or extract of liquorice to conceal its disagreeable taste. Iodide of potassium is another salt which often does good service in chronic bronchitis.

In cases in which there is excessive exudation and secretion from the surface of the mucous membrane balsamic remedies are applicable—tolu, benzoin, Peruvian balsam, benzoic acid; or, again, one may prescribe copaiba, turpentine, ammoniacum, or one of the fœtid gum resins, such as assafœtida.

Of late years several physicians, in Germany especially, have made large use of compressed air, and also of rarefied air, in the treatment of various bronchial and pulmonary affections. In the earlier attempts recourse was had to pneumatic chambers, made somewhat after the fashion of the diving-bell, in which the patients sat for an hour at a time, under a pressure of $1\frac{2}{5}$ to $1\frac{3}{7}$ atmospheres. It is obviously in very exceptional circumstances only that such elaborate constructions can be available in practice; and therefore attention has been more recently devoted chiefly to the invention of portable forms of apparatus, by which the patient is made to inhale air of varying degrees of pressure without being himself immersed in it. Most of these instruments are upon the principle of the ordinary gasometer used to receive coal gas at gas-works; an air-containing cylinder, open below, is suspended in another cylinder, open above, so that the one can move freely up and down within the other. By pouring more or less of water into the outer cylinder, and then either pressing down the inner cylinder with weights or lifting it up to varying heights, the air inside it may be compressed; or it may be rarefied to any desired extent. The object is to make the patient *inspire* compressed air, or *expire* into rarefied air. A tube from the inner cylinder is connected with a mask, which can be fitted air-tight over the nose and the mouth. There is a stopcock, which is turned by the patient each time he breathes, so that the mask communicates with the cylinder either during inspiration or during expiration (as may be intended), whereas on reversing the movement it communicates with the external air. Waldenburg, who invented this machine, usually directs that compressed air should be inspired for five, ten, or fifteen minutes, and then, after a pause, that expiration into rarefied air should be practised for a similar period. The range of pressure variations employed is but small. In most cases two or three sittings a day are sufficient. It is obvious that, so far as emphysema is concerned,

the greatest degree of benefit is to be anticipated from expiration into rarefied air. The inspiration of compressed air, when the whole body is not immersed in a pneumatic chamber, might be expected to tend rather towards increasing the distension of the pulmonary alveoli. But, on the other hand, it is said that expiration into rarefied air may, in its turn, do harm by augmenting the flow of blood to the bronchial mucous membrane, whereas inspiration of compressed air has the effect of increasing the blood-pressure in the systemic vessels, and of unloading the pulmonary vessels and the right side of the heart. It is therefore best to alternate the two methods, as Waldenburg and others advise. There is strong testimony of the beneficial action of this mode of treatment, in augmenting (at least for a time) the activity of emphysematous lungs, and in relieving the symptoms of bronchial catarrh. (See Dr Theodore Williams' three lectures in the 'British Medical Journal,' April 18th, 1885; Dr Gamgee's paper, *ibid.*, December 18th, 1886; and the chapter in Dr Hale White's little book on non-medicinal therapeutics.)

In some cases of chronic bronchitis recourse may be had with advantage to certain Continental spas. According to Braun those waters are the best which contain a considerable amount of chloride of sodium, as well as of carbonate of soda, such as Ems in Germany and Mont Dore in France.

The diet of patients suffering from chronic bronchitis requires regulation. Rather free diluents are in most cases desirable, and probably the mineral waters just mentioned act chiefly in this way, promoting free and loose secretion from the bronchial mucous membrane. By common experience beer does harm, and even London labourers with a cough avoid porter, and drink gin instead. Cheese is also believed to be bad for a cough; and Pliny's dictum—*nuces tussientibus inimicæ*—still holds good, probably from the mechanical irritation of the fauces which they produce.

When it is thought desirable for a bronchitic patient to spend the winter and spring away from home, the choice lies usually between climates which are soft and "sedative" (such as Torquay, Falmouth, Penzance, Pau, Madeira), those which are stimulant without too much risk of exposure to cold winds (as Mentone and San Remo), and those which are surrounded by pine woods (as Arcachon and Bournemouth).

PLASTIC BRONCHITIS.*—This singular affection is certainly nothing else than bronchitis anatomically; but it has characters so peculiar that from a clinical point of view it would be absurd to group it with the ordinary catarrhal forms. It consists in the exudation of a fibrinous material from the walls of the air-passages which forms "casts" of their channels. A like exudation may occur by extension of a morbid process downwards from the larynx in diphtheria, and much less frequently by extension upwards from the pulmonary alveoli in pneumonia. But these are totally different in pathology and symptoms. The former has been described with membranous laryngitis in the chapter on Diphtheria. The latter will be again mentioned in that on Pneumonia.

The disease is one of the rarest that are known to physicians—"an affection of great rarity" (Walshe); "höchstselten" (Riegel); "aeusserstselten" (Biermer). The experience of Sir Thomas Watson was remarkable, in having had under his own observation five well-marked examples.

* *Synonyms.*—Fibrinous bronchitis—Croupous bronchitis or Bronchial croup of the German writers—Bronchial polypi of older authors—Angina polyposa.

These "bronchial polypi" were known very early. Dr Nicholas Tulp (the lecturer in Rembrandt's famous painting, "The Lesson of Anatomy") records and figures two specimens brought up by a Dutch sea-captain suffering from hæmoptysis: "*Effudit duos insignes venarum ramos, adæquantes singulos expansæ manûs magnitudinem*" ('Obs. Med.,' Amst. Elz., 1652, cap. xiii, p. 122, tab. iii, iv). Afterwards cases were recorded by the younger Bartholin, Cheselden, de Haen, Morgagni, Hunter,* Cheyne of Dublin, and Stokes. Most of the early cases (1690—1730) were published in the 'Philosophical Transactions.'

Anatomy.—In almost all cases of plastic bronchitis the patient soon begins to expectorate masses of the peculiar exudation. It usually appears rolled up into a sort of ball, with a good deal of mucus and blood covering it. All this is easily removed by floating it out in water, and one then sees that there is a complete cast of some part of the bronchial tree, extending perhaps down to its finest subdivisions, so that, according to Biermer, the minute terminal filaments may actually show bulbous ends moulded in the infundibula themselves. The colour of the cast is whitish yellow or grey; its consistence is tough and elastic; it is almost always made up of a number of concentric laminæ, separated here and there by narrow spaces and with a more or less definite central cavity, containing mucus or bubbles of air. The more delicate filaments are said to be generally solid.

The laminated structure affords a distinction from the branching clots which are sometimes formed in the air-passages as the result of hæmorrhage, and which are quite homogeneous. Biermer, indeed, is disposed to deny that blood ever coagulates so as to form casts of the bronchial tree. But Dr Walshe speaks of it in the most positive terms, and there could hardly be a better authority.

The casts in cases of fibrinous bronchitis, when examined microscopically, are seen to consist of a hyaline or slightly fibrillated base, in which are embedded large numbers of leucocytes. They seldom contain red blood-discs in any quantity. Several observers have noticed Charcot's crystals in them. In one case Waldenburg found that the thicker parts contained only a few formed elements, but very abundant fat-globules.

The length of a bronchial cast is commonly from one and a half to two and a half inches, but sometimes it may be four or five inches, or even (as in a case of Riegel's) six or seven inches. The diameter of the thickest part of it is seldom greater than that of a goose-quill, being in fact considerably less than that of the space in which it was formed. Biermer has pointed out that from its appearance one can sometimes draw an inference as to the part of the lung from which it came, whether from the short rapidly branching tubes of the upper lobe, or from the comparatively longer tubes of the lower lobe. The masses expectorated at different times by the same patient often resemble one another so exactly in size and in the arrangement of their subdivisions as clearly to show that they have all in succession been derived from the same tract of mucous membrane. For example, in a case recorded by Kretschy seven casts appeared one after the other, all of which came from the middle and lower lobes of the right lung. In fatal cases it is not usually found that the tubes which have poured out the fibrinous

* Hunter's case occurs as a short Appendix to his 'Treatise on the Blood, Inflammation, and Gunshot Wounds.' The patient was a man of twenty-two, who spat mucus often mixed with blood. He recovered. The figure agrees with those illustrating the cases of Fuller, Peacock, Salter, Tuckwell, and the author of the present work, in the 'Pathological Transactions' (vols. v, ix, xvi, and xxi).

exudation show any marked morbid changes. The mucous membrane is sometimes reddened, sometimes pale and healthy-looking. In two instances Biermer found the epithelium still remaining beneath loose casts; but he was himself disposed to think that these cases might be exceptional; and Kretschy has since stated that in his case there was no trace of epithelium in that part of the air-passages which contained the plastic material. The submucous tissue may be swollen and infiltrated with serum. The pulmonary alveoli are usually unaffected, but they have been found sometimes collapsed, sometimes over-distended.

Symptoms.—The expectoration of casts of the lower air-passages is generally attended with severe cough and dyspnœa, the occurrence of which may be the first indication that the patient is otherwise than well. But in many cases there is an antecedent stage during which he appears to be suffering from ordinary bronchial catarrh; and this may last for a long time. Sometimes the disease sets in with rigors, loss of appetite, thirst, oppression of the chest, and pyrexia, so that it may be supposed that an attack of pneumonia is impending. Presently a dry, hard cough appears, which may cause extreme suffering; the breathing becomes rapid, up to 40 or more in the minute; it may be attended with the greatest anguish, as of impending suffocation, with lividity, and with a small tense pulse. There may be some pain in the side, and a feeling of soreness within the chest, but on the whole the attack is more distressing than acutely painful. At first nothing is expectorated, or only a little mucus. The cough may even, it is said, go on for days before any fibrinous masses appear. More often a cast is detached and got rid of after a few hours, and by this the cough and dyspnœa are generally at once relieved, at least for a time. Hæmoptysis often occurs at intervals during the paroxysm, not only at the time when the cast is being expectorated, but also previously. The quantity of blood is not large; perhaps it amounts to a tablespoonful at a time. The case of the late Prof. Daniell, recorded by Watson, is exceptional in the fact that from two to eight ounces were spat on each occasion.

Physical signs.—Examination of the chest throws little light upon cases of plastic bronchitis. If a large tube is blocked, absence of vesicular murmur may be made out over some part of one of the lungs. The fact that the violent cough fails to clear away the obstacle might perhaps suggest to a keen observer the presence of something more than a plug of mucus such as may prevent the entrance of air in ordinary cases of catarrhal bronchitis, and the diagnosis as to the cause of the obstruction would then lie between fibrinous casts, a foreign body, and stenosis of the walls of the tube. In practice, however, it scarcely ever happens that any suspicion of the real nature of the case arises until a cast has actually been expectorated. There is not usually any change in the percussion-sound, but Dr Walshe says that he has had repeated occasion to observe dulness, as complete as that of pneumonic consolidation, dependent upon collapse of the lung-substance. He also says that local pneumonia now and then occurs, attended with crepitation and with bronchial breathing, as well as with rusty sputa. When there is extensive blocking of tubes the movements of the corresponding side of the chest may be distinctly impeded, and the lower ribs may even be drawn in during inspiration. Râles are sometimes audible over the affected part of the lung, especially when the cast is becoming loose; some writers have described special sounds as thus produced, but it does not appear that they are really characteristic.

Course.—The expectoration of a single cast very rarely brings an attack of plastic bronchitis to an end. As a rule the relief is only temporary. After some hours the cough and the dyspnœa return, and are followed by the appearance of another cast. This process is usually repeated about once in twenty-four or in forty-eight hours for several days, and then the affection slowly subsides. Smaller pieces may be spat up at very frequent intervals; being embedded in mucus, they sometimes remain unnoticed unless specially looked for.

Prognosis.—It may well be supposed that the expulsion of such large masses as sometimes come from the air-passages in this disease is not unattended with danger. In 1865 the author showed to the Pathological Society a cast which was taken from the body of a girl aged seven, having been found lying across the bifurcation of the trachea, with its branches extending into the ramification of the right bronchus, but with its broad end occluding the left bronchus. She had been expectorating similar masses for three days; and on the very day on which she died she had already, at 3 a.m., brought up a cast of about the same size as that which killed her at 3 p.m. in a violent fit of cough and dyspnœa. It is therefore clear that Dr Walshe and others go too far in giving a favourable prognosis in cases of plastic bronchitis without reservation. Lebert, in a paper in the 'Deutsches Archiv' for 1869, divides 44 cases (collected from various sources) into acute and chronic: of seventeen of the former, four ended fatally; of twenty-seven of the latter, only three. The distinction, however, appears to be rather artificial; and one of the four fatal acute cases, that recorded by Nonat, was, there is reason to suspect, a case of diphtheria. As a rule, when death occurs, it is caused by extension of the disease into so large a part of the bronchial tree that due aëration of the blood can no longer be effected, and is preceded by stupor and somnolence. Riegel, however, relates a case in which, although the patient died in an attack of asphyxia, after spitting up large casts nearly every day for three weeks, the air-passages were all found empty after death.

Lebert placed in a separate category cases in which plastic bronchitis has run on to a fatal termination without any fibrinous masses having been expectorated. As they occurred chiefly in children, and generally in association with broncho-pneumonia after measles, they should probably be regarded as different from plastic bronchitis.

Recurrence.—When an attack of fibrinous bronchitis has passed off, leaving the patient apparently well, it by no means follows that the disease is really at an end. One of the most curious points about it is its liability to return again and again at irregular intervals, sometimes during a very long period. Dr Walshe met with an instance in which the expectoration of casts continued, with occasional brief intermissions, from the spring of 1843 to June, 1857, when he lost sight of the patient. In the course of this time she married, and lived at Buenos Ayres for four months. Other observers have recorded cases which were scarcely less protracted; in many of them the general health seemed to remain unaffected.

Ætiology.—With regard to the causes of plastic bronchitis, scarcely anything can as yet be said. It is much more common in males than in females.

The period of life at which it is most frequent is between ten and thirty. One case, recorded at the advanced age of seventy-two, had lasted seven or eight years.

Adding to the 31 cases tabulated by the late Dr Peacock in the fifth volume of the 'Pathological Transactions' 24 additional ones collected from various sources, we find that of these 55 cases, 42 occurred in men and 13 in women. (Biermer's figures are 39 male to 19 female patients.) Of 37 patients whose ages are given, 5 were between five and ten, 12 between eleven and twenty, 10 between twenty-one and thirty, 8 between thirty-one and fifty, and 2 between fifty-one and sixty.

The writer has had only two typical cases under his care, one a boy of twelve, about 1870, who spat up repeated casts with some amount of blood, and recovered; the other a man of forty-three, who died of acute pneumonia (May, 1890) in the course of one of repeated attacks of bronchitis with expectoration of large fibrinous casts. A third case (published in the 'Pathological Transactions' for 1880, p. 30), in a woman of thirty-two, was fatal after tracheotomy, but here the trachea and primary bronchi were affected, so that a continuous fibrinous cast was brought up; and clinically as well as pathologically the case was peculiar.

A remarkable circumstance, all the more striking because of the extreme rarity of the disease, is its occurrence in different members of the same family. Fuller met with it in two sisters; Watson relates the cases of two brothers, both of whom were affected within a twelvemonth.

Plastic bronchitis is supposed to be rarer in southern countries than in the north of Europe. Riegel says that, like acute pneumonia, it is most apt to occur towards the end of spring, when there are great daily variations of temperature. In one instance the recurrence of the attacks appeared to be connected with the catamenial periods. Eisenlohr met with a case in which fibrinous casts were expectorated during the second week of enteric fever.

There seems no reason to suppose that this remarkable affection is at all related to phthisis.

Treatment seems generally to be altogether ineffectual. Waldenburg, however, saw a case in a girl, aged eight and a half, who for more than four years had been coughing up fibrinous masses at intervals of a few days, and in whom a whey cure and the daily inhalation of lime-water succeeded in arresting the disease in six or seven weeks. Indeed, a spray of lime-water, or a solution of an alkaline carbonate, should always be employed in plastic bronchitis; the only doubt is whether they reach the lower air-passages in sufficient quantity. Emetics appear to be sometimes useful: probably it is best to use apomorphia hypodermically. Biermer recommends an active mercurial treatment; others have prescribed iodide of potassium with apparent advantage.

Dr Walshe believes that neither inhalation of iodine, nor exhibition of alkaline medicines, nor the best of general health, nor the most favoured climates, have the least beneficial effect in preventing or curing the attacks of this paradoxical disorder.

PNEUMONIA

AND INFLAMMATION OF THE LUNGS

"Spiritus gravis est ac fervidus. Facies rubet, et in ea præsertim malæ. Quod in oculis album est humidissimum et pingue apparet: acumen nasi simum fit; venæ in temporibus et cervice elatæ sunt: cibi fastidium. Pulsus in initio mali magnus, vacuus, creberrimus, quasi compressus. Calor in exterioribus partibus obscurus et humidior; in interioribus autem aridus atque ferventissimus; ex quo spiritus incalescit, sitis fit, et linguæ siccitas, et frigidi aeris desiderium, et animi molestia. Accedit etiam tussis, quæ plerumque sicca est, vel si quidquam excreatur pituita prodit, aut squamans, aut bile saturata, vel cruenta et coloris floridissimi."—ARETÆUS.

BY *pneumonia* (the peripneumony of older writers), which in Greek medicine denoted "disease of the lungs," is now understood an inflammation of the texture of the lungs, and when the term is used without qualification, one that is acute and primary.

It corresponds to the anatomical condition known as hepatisation and due to exudation into the alveoli.

With qualifications the word is applied much more widely, to any form of pulmonary inflammation. In the sense now employed, it excludes (1) that form of lobular inflammation of the lungs which arises by extension from the bronchial tubes, and has been called catarrhal or lobular or *broncho-pneumonia*; (2) the suppurative or *pyæmic lobular pneumonia* which occurs as

* *Synonyms.*—Peripneumony—Fibrinous, Plastic, or Croupous pneumonia—Acute or Sthenic pneumonia—Lobar pneumonia—Acute inflammation of the lungs.

Περιπνευμονία (or in the Attic form *περιπλευμονία*), from *πνεύμων* or *πλεύμων* (whence *pulmo*), the lung, occurs in Hippocrates and Plato. It did not originally carry with it the notion of an inflammatory or febrile disorder. The prefix peri- was only dropped in the present century.

The Germans have adopted the designation of "croupous," because the exudation mainly consists of a fibrinous material like that of croup. In fact, "croupous" means "fibrinous" or "plastic." To English ears, however, this has an awkward sound, and the phrase is on other grounds objectionable. It suggests some connection with the malady known as croup, whereas there is none; and it confounds a clinical term with an anatomical condition.

the result of infective embolism; (3) *traumatic pneumonia* from wounds of the lung, injuries of the chest, or the penetration of foreign bodies into the air-passages. (4) It is a question whether the congestive or *hypostatic pneumonia* which so often forms the immediate cause of death in persons suffering from almost any chronic or acute disease, particularly enteric fever, ought not to be placed under a separate head. (5) There is no question that the *caseous pneumonia* which destroys the lung in phthisis must be separated from other kinds of pulmonary inflammation. (6) Lastly, chronic fibrous *interstitial pneumonia* is a distinct process both clinically and pathologically, whether it occurs as a conservative element in phthisis, or by extension from the peribronchial connective tissue and the pleura, and whether tubercular, traumatic, or syphilitic in origin.

Each of these so-called forms or varieties of pneumonia requires carefully chosen adjectives to discriminate it, and it would be well if each had a distinctive and substantive name. But when the term pneumonia is used without a qualifying epithet, it is generally understood (except perhaps in the case of children) to refer to the classical peripneumony.

For the sake of distinction, we may define the pneumonia now to be discussed as *idiopathic* in its origin, *acute* in its course, *lobar* in its extent, *basal* in its usual distribution, and *fibrinous* in the character of its exudation.

It is true that lobular and pyæmic inflammations of the lung are often acute, that idiopathic is at best a negative phrase, that the disease often exceeds and sometimes falls short of occupying a complete lobe, and that it may affect the apex of the lung; hence no adjective is quite satisfactory. Nevertheless we shall see that in its natural history and its clinical features, as well as in its anatomy, pneumonia in the restricted sense of the term is one of the most peculiar and distinctive of diseases.

Morbid anatomy.—The pneumonic process consists of a series of changes by which the spongy pulmonary tissue is rapidly converted into a solid mass. Systematic writers describe several distinct stages.

The first is the stage of "active congestion" or *engorgement*. The affected part of the lung is massive, heavy, and dark red in colour. It pits under the pressure of the finger, and a reddish frothy serum oozes from its cut surface; if the pressure is increased, its substance breaks down. Microscopically, the most obvious appearance is the dilated and tortuous state of the capillaries of the alveolar walls; minute punctiform hæmorrhages are also to be seen in the connective tissue between the lobules and beneath the pleura.

Next comes the stage of *red hepatisation*, so called because the texture of the lung is solid, like liver. It now sinks in water, it does not crepitate when pressed between the finger and the thumb, it is easily broken, and little or no fluid can be squeezed from it. Its cut surface has a dull, lustreless appearance, and is distinctly granular. The granules are composed of a solid inflammatory exudation, which completely fills up both alveoli and infundibula. Rindfleisch gives drawings of masses of it obtained by scraping the cut surface; they form complete casts of the interior of the spaces in which they were moulded. The red colour of the lung at this period is probably due partly to the large quantity of blood in its capillaries, partly to the fact that great numbers of red discs are extravasated and mingled with the coagulated fibrin and exuded leucocytes.

The third stage is that of *grey hepatisation*. This is characterised not only by a change in the colour of the affected parts of the lung-substance,

which now passes through reddish grey to grey or whitish yellow, but also by the diseased tissue becoming even softer than before, by its being less markedly granular on section, and by its beginning to exude on pressure a turbid fluid, more or less opaque, white, and puriform. The extreme forms of grey hepatisation are, in fact, described by some pathologists as constituting a fourth stage, which they term *purulent infiltration*. Histologically there is a wide difference between the characters of "red" and those of "grey hepatisation." In the grey stage no fibrinous coagula are visible; the substance which fills the alveoli now appears to consist merely of a mass of crowded leucocytes. The extravasated red discs are no longer to be seen. Rindfleisch speaks of them as becoming decolourised; perhaps we may suppose that they are absorbed by the rapidly multiplying leucocytes. To account for the change of colour it must also be assumed that the increased amount of exudation compresses the pulmonary capillaries and drives the blood out of them. But Rindfleisch remarks that it would be a great mistake to imagine that this occurs during life to the same extent as after death. He finds that in the dead body it is always easy to inject the vessels, and he therefore concludes that the heart, so long as it is beating, must be able to keep up a more or less active circulation through them. In other words, it is probable that the grey colour is, strictly speaking, a cadaveric change dependent on failure of the circulation after death.

The most important histological distinction between the two kinds of hepatisation is afforded by the state of the alveolar walls. In the "red" stage they are unaltered, except that their capillaries are distended; in the "grey" stage they are infiltrated with leucocytes, which fill up every interstice.

Distribution.—Pneumonia attacks parts of the lungs only, never the whole at once. It almost always begins at some one spot, from which it rapidly spreads.

All observers are agreed that the *right* lung is more often the seat of pneumonia than the left, the proportion being about as five to three. Sometimes both lungs are attacked together or, more often, in succession. On either side the *lower lobe* is affected far more frequently than any other part; Jürgensen says that it escapes altogether only in one case out of four, and probably this is above the mark. As a rule hepatisation begins at the extreme base, and extends gradually upwards from day to day; but sometimes it spreads downwards from the summit of the lower lobe, or upwards and downwards from its middle, or backwards from the anterior border. In the upper lobe it may either pass from the apex downwards, or from below upwards and forwards. Sometimes its distribution remains strictly limited by the lobar septa; sometimes its spreading edge forms a horizontal line, ignoring them altogether. The most common seat of pneumonia is the right base, next the left base, next both bases. Even at the apex left pneumonia is more rare than right. Henoch found right apex pneumonia in 21, and left apex pneumonia in only 4 cases out of 74 of lobar pneumonia in children. Dr Goodhart's numbers are 18 right and 17 left apex pneumonia out of 120 cases of lobar pneumonia in children.

Events.—The results of pneumonia are unlike those of ordinary inflammation. Either death occurs, or the whole affected tissue clears up and returns to its former condition. The formation of an *abscess* in the lung, as the result of true pneumonia, is admitted by all writers to be very rare, and

many, including the present writer, doubt whether it ever occurs. Cases have, indeed, been recorded; but the question is whether a more accurate pathology might not have led to a different interpretation. They may have been circumscribed empyema, or suppurating bronchial sacs or hydatids; or true pulmonary abscesses, but not of pneumonic origin—traumatic, pyæmic, or gangrenous. The termination of pneumonia in *gangrene*, though also very infrequent, undoubtedly occurs under special circumstances to be afterwards discussed (*infra*, p. 1014).

Pneumonia often ends by *resolution*, and the question then presents itself whether it is possible for the disease to pass through all its three stages above described and yet for the lung to recover. It is certain that many cases end favourably after there has been clear evidence from physical signs that the pulmonary tissue has become "consolidated," *i. e.* has reached the stage of red hepatisation; the only doubt is whether the supervention of the third stage of grey hepatisation is compatible with recovery. In their work on Pathological Anatomy, Wilks and Moxon express a decided opinion that in most cases the disease has not advanced far beyond the "red" stage when resolution begins.

There are obviously two ways in which the pulmonary alveoli may be emptied of the exudation that fills them: one is by its escaping into the air-passages and being expectorated; the other by its being reabsorbed into the blood. Rindfleisch maintains that the greater portion takes the former course; but most clinical physicians will agree with Jürgensen (in the article on pneumonia in 'Ziemssen's Handbuch') that he is mistaken, inasmuch as in many cases sputum is altogether wanting.

After the subsidence of pneumonia, if the patient should die at no long interval from some other disease, the lung is found to have nearly regained its healthy appearance, but to be slightly redder and tougher than natural. Two such cases at least have been observed at Guy's Hospital, but unfortunately no microscopical investigations were made as to the exact state of the pulmonary tissue. Rindfleisch speaks of a loss of elasticity as resulting from pneumonia, and as continuing a long time after recovery.

It is a very important question whether, instead of subsiding, true pneumonia ever leads to permanent changes in the lung, to the development of fibrous tissue, constituting what is termed cirrhosis or chronic pneumonia, or to a destructive process, ending in the formation of cavities more or less like those of phthisis. As regards cirrhosis, though some observers (including Wilks) are opposed to the belief that it ever arises in this way, cases will hereafter be cited which seem to point to its occurrence. It is, at all events, extremely rare. As for the supposed termination of pneumonia in phthisis, there is every reason to believe that the cases that have been so interpreted were phthisical from the beginning.

Concomitant post-mortem lesions.—Pleurisy of the dry kind is a constant part of the disease. Wherever the hepatisation reaches the surface of the lung, the corresponding part of the pleura always becomes covered with lymph. Accordingly some physicians speak of the disease as "pleuro-pneumonia," at least in those cases in which they discover physical evidence of pleurisy during life. But this seems to be an unnecessary refinement, and indeed to be rather misleading, since after death the dry exudation of pleurisy is found, even when there had been no signs of its presence during life. It is better to reserve the term pleuro-pneumonia for cases in which the pleurisy leads to fluid effusion, and so becomes of clinical importance.

Occasionally there is likewise *pericarditis*, which has probably arisen by extension from the pleura. Still more rarely the peritoneum also, especially the upper part of it, is found coated with lymph. Sometimes the mediastinal tissues are extensively infiltrated with a gelatinous exudation.

The bronchial lymph-glands are constantly found enlarged, pinkish grey, and soft. The subpleural lymphatics corresponding with the seat of the pneumonia may be not infrequently observed to be distended with inflammatory products, so as to give a marbled appearance to the surface.

As a very rare complication of pneumonia must be mentioned acute meningitis. Four cases have been already narrated (p. 649); two of these were cerebro-spinal meningitis; one was complicated by diphtheria, one by chronic Bright's disease, and one by the possibility of a traumatic or pyæmic origin.

Less infrequent is ulceration of the larynx; the ulcers are found over the arytænoid cartilages, just where they occur from many other causes.

Probably it is to the pyrexia which accompanies pneumonia that one should refer some other slight but almost constant morbid changes that are met with after death—a moderate degree of enlargement with softening of the spleen, slight catarrh of the intestine, and cloudy swelling of the kidneys.

Signs.—It is by physical examination alone that the seat and extent of pneumonia can from day to day be determined with accuracy, although the other symptoms commonly enable one to form a confident opinion of the nature of the disease.

The earliest signs are generally recognised by auscultation. According to Stokes, there is first audible a peculiar harshness of the vesicular murmur. But more often the first sign detected is an entirely new or adventitious sound which is called *pneumonic crepitation*, or sometimes "fine crepitation."* This is exactly like the sound produced by rubbing a lock of hair between the fingers close to one's ear, a comparison suggested by Dr C. J. B. Williams.† By Laennec, who discovered it, it was supposed to be pathognomonic of pneumonia. But sometimes it is not heard in undoubted cases of this disease, and it is now known to occur occasionally from œdema of the lungs. A sound very like it, if not absolutely the same, may often be heard with successive inspirations in the bases of the lungs of a person who has been lying on the back with some febrile disease, if he is made to sit up and breathe deeply, so as to fill those parts which have been for some time disused. In the last case there can be no doubt that the cause of the sound is the opening up of portions of the tissue that had become collapsed; and almost all observers are now agreed that in pneumonia it has a similar origin, being due to the inspiratory separation of the walls of alveoli and bronchioles which, being swollen, had come into contact in expiration. Crepitation is, indeed, heard only during inspiration, and sometimes only just at the end of deep inspiration, as after coughing. Its mechanism is therefore not that of other râles, whether crepitant or non-consonating; it

* *Fr.* Râle crépitant.—*Germ.* Das knisternde Rasseln.

† It is much "smaller" than any other râle, and would not be recognised as due to bursting of bubbles, like gurgling or mucous rattles. It is consonating, musical in character, and high-pitched in note. Laennec calls it "une espèce de crépitation ou de râle léger, dont le bruit peut être comparé à celui du sel que l'on fait décrépiter en le chauffant dans une bassine."

does not depend on the bursting of bubbles, and should always be distinguished from true "moist sounds."

One must search carefully for this important sign before concluding that it is not present. But, on the other hand, the fact must be admitted that in many cases of pneumonia this sign is not at any time discovered. Whether it is ever really altogether absent in such cases is perhaps doubtful, because it is in its nature transitory, and so may have passed off before an examination of the chest is made. Sometimes, however, it remains audible during almost the whole of the disease, not, indeed, at the same spot, for where there is complete consolidation it almost necessarily disappears; but in one spot after another, as they are successively attacked by the inflammatory process.

As the state of engorgement passes on to that of red hepatisation, there are developed other signs—dulness on percussion, bronchial breathing, and bronchophony with increased tactile vibration.

The degree of *dulness* varies much in different cases. It is not so absolute as in cases of fluid effusion into the pleura; nor is the sense of resistance to the finger so great. In exceptional cases the percussion-sound undergoes very curious modifications, the explanation of which is by no means obvious. Thus a cracked-pot sound is sometimes elicited; this is attributed by Dr Gee to the presence of "islets" of unsolidified lung embedded in the substance of the hepatised tissue. In other rare cases the sound has a more or less marked tympanitic quality. Sometimes the spot where this tympanitic sound is heard is not directly over the consolidated part of the lung, but in its neighbourhood, over pulmonary tissue which may be supposed to be relaxed as the result of the increased bulk of the consolidated part. Thus hepatisation of the upper lobe of the lung behind may cause a tympanitic percussion-note beneath the clavicle on the same side.

The *bronchial breathing* that accompanies the second stage of pneumonia may exhibit every variety of quality up to the amphoric. Usually it is a typical in-and-out, whiffing, tubular sound, equal with expiration and inspiration, and in quality not unlike a to-and-fro bellows murmur of the heart. Occasionally no such sounds are audible, and the explanation doubtless is that the tubes passing to the consolidated part happen to be filled with fibrinous plugs.

Bronchophony generally goes with bronchial breathing, and presents like differences of degree. Dr Gee remarks that in infants a bronchophonic cry is often the only auscultatory sign that can be obtained.

Increase of vocal fremitus, although sometimes well marked, is by no means constant. Probably its occurrence depends upon the state of the tubes leading to the consolidated part. If they are full of fluid secretion, the transmission downwards of the vocal vibrations is interrupted. It is only when the left side is the one on which the fremitus is greater that this sign can be regarded as of high clinical importance, because on the right side it is very often greater in healthy persons.

Lastly, when pneumonia affects only the central part of the lung, or reaches no part of the surface except that which is in contact with the diaphragm, physical signs are altogether absent. What is more common is for the disease to begin deeply in the interior, but to become superficial a few days later, so that all doubt as to the nature of the case is soon at an end.

During the stage of *resolution* the peculiar auscultatory signs of hepatisa-

tion disappear, and they are commonly replaced by râles, which may vary widely in character. Sometimes a crepitation is now heard, which may be scarcely less fine than that of the early period of the disease; this is called *crepitatio redux*. In other cases the sounds are so large, and at the same time so highly consonating in quality, that one might imagine the patient to be at an advanced period of phthisis, with the lung breaking up in all directions. Yet after a few days these sounds in their turn cease to be audible. A considerable time generally passes before the vesicular murmur becomes as loud and as distinct as it normally should be. The percussion-resonance also may long remain deficient, even when there has been no pleuritic effusion.

Clinical course.—An attack of pneumonia commonly sets in suddenly with a well-marked rigor. This occurred in 241 out of 280 cases, and again in 782 out of 975 cases ('Collective Investigation Record'). Sometimes, however, there is not more than a sensation of chilliness, which may almost escape notice. Sometimes, particularly in children, the disease is ushered in by a convulsive seizure, or by vomiting. As a rare exception when the pneumonia is idiopathic, but most frequently when it supervenes as a secondary complication of other diseases, its onset is insidious, and there are no symptoms to mark the exact time at which it begins.

Pyrexia develops very rapidly. Jürgensen cites a number of observations which show that the temperature may reach 104°, or even a higher point, within three or four hours from the shivering. At the same time the pulse is quickened, and becomes full and bounding in character. There are the usual complaints of malaise, headache, pains in the limbs, and anorexia, as in every other febrile disease. As the rigor passes off the cheeks acquire a crimson flush. A point on which Addison used to lay great stress is that, as tested by the hand, there is in pneumonia a pungent dry heat of skin hardly observed in any other affection. We saw how this has since been confirmed by the observations of Schülein (p. 37); and it agrees with the description of Aretæus: *calor aridus atque ferventissimus.*

So far there is nothing in the symptoms to show that the thoracic organs are the seat of the patient's illness. Before auscultation was practised it was not uncommon for a case of pneumonia to be called "typhus" or "continued fever," and for the autopsy to show for the first time the real nature of the case. Or if, as sometimes happens, there was violent delirium from the very commencement, and the patient became comatose and died in twenty-four or thirty-six hours, the disease was set down as "meningitis" or "encephalitis." But even then a careful observer seldom failed to notice indications that led him to form a correct judgment.

One point of great importance, on which Walshe especially insisted, is a change in the ratio of the pulse to the respiration. Healthy persons breathe once for every four or four and a half pulsations of the heart. In febrile diseases generally, both pulse and respiration are more frequent; but the relation between them is not much, if at all, disturbed. In pneumonia the increased frequency of the respiration is out of proportion to that of the pulse, the ratio being as one to three, or one to two, or higher still; for the patient may breathe sixty or eighty times a minute. Walshe has observed the number of respirations in the minute actually greater than that of the heart-beats. Jürgensen says that the cases in which this occurs are those of old people with slowly-acting hearts and atheromatous vessels. It is a curious fact, as Walshe remarks, that the amount of subjective

distress produced by such rapidity of breathing varies extremely in different cases; some patients, breathing thirty, forty, or even sixty times a minute, are wholly unconscious of any dyspnœa.

Another indication that should draw attention to the respiratory organs as the probable seat of the disease is, that the nostrils work during inspiration, and that the sterno-mastoidei and trapezii are tense and prominent. It may also be observed that the flushed cheeks and the lips have a slightly purplish tint. At present every educated practitioner, after noticing the aspect, and ascertaining the state of the pulse, respiration, and temperature of the patient, examines in every case, as a matter of routine, at least the apices of the lungs in front and their bases behind. Even with careful scrutiny, however, there is sometimes complete absence of the physical signs above described for the first twenty-four or forty-eight hours, a fact which is important to remember in forming a diagnosis. In marked cases the flushed face, erect posture, anxious look, bright eye, and rapid breathing, with the herpes of the lips, give a *facies* which is very characteristic.

Moreover, there are often symptoms which point clearly to the true nature of the illness, and show which side of the chest is affected.

One such symptom is *pain*. This is commonly situated near the nipple or towards the axilla, and may be the first symptom which the patient notices. This pain is identical with the *point de côté* of pleurisy; and in all probability, in cases of pneumonia, it is really due to the coincident pleurisy, as Addison long ago taught. Sometimes the pain does not appear until the patient has been ill some hours, or not until the second day, and it may be entirely absent.* It is exceedingly severe, and being increased by every movement, it leads the patient to endeavour to fix the ribs by pressure with his hand, and also causes him to curve his spine towards that side, so as to bring the ribs as close to one another as possible. Sometimes the act of drinking produces so much suffering that the patient will endure the great thirst produced by the disease rather than attempt to swallow.

The *cough*, which is another early symptom, is also modified by the pain, which interrupts and as far as possible cuts it short. The distress caused by the cough is greatly increased by the fact that the *expectoration* in pneumonia, though very scanty, is singularly tenacious and viscid, so that it is got rid of with extreme difficulty; even when it has reached the lips it often clings to them, and can only be removed by the handkerchief; and it adheres equally firmly to the spittoon, which can be inverted without any of it escaping. Pneumonic sputum has also a peculiar colour, due to the circumstance that the frothy mucus of which it consists is intimately mixed with blood that has perhaps undergone slight chemical changes since it left the vessels. This colour varies in shade in different cases. It is usually bright orange, tawny, or like the rust of iron, so that it is commonly called "rusty" expectoration. But sometimes the tint is a paler apple-yellow, and sometimes it is the bright scarlet tint of unaltered blood. Spitting of pure blood in such quantity as to deserve the name of hæmoptysis is not common; but it may occur in cases uncomplicated by tubercle, purpura, or Bright's disease, and the result may be as good and speedy a recovery as usual.

In some cases the sputum is thin, watery, and of a brownish-red colour, so that it is compared with prune-juice or liquorice-water. Such sputum is seen chiefly at advanced stages of the disease, and when it is taking an

* So Celsus: "*Id genus morbi (quod περιπνευμονικὸν Græci vocant) plus periculi quam doloris habet*" (iv, 7).

unfavourable course; but it may be present at an early period, and in cases that ultimately do well. Possibly, as Dr Wilson Fox suggested, it comes from a part of the lung affected with œdema.

Some patients, usually children, have no cough, and therefore no expectoration, throughout the whole course of pneumonia.

Remak showed, many years ago, that in pneumonic sputum there can sometimes be detected with the microscope branching fibrinous casts of the smallest bronchial tubes. Micrococci are often present (p. 997).

Having thus developed itself, pneumonia commonly runs on for some days with but little change. As more of the pulmonary tissue undergoes hepatisation, the physical signs become more marked; but there is often no corresponding increase in the severity of the symptoms.

The type of the *pyrexia* is, as a rule, continuous, with the usual diurnal oscillations. Wunderlich, however, states that it is not uncommon for an irregular and sudden elevation of temperature to occur, which is followed by a no less sudden fall through as many as 7° or even 9° F. to the normal point or below it, and that again in a few hours by a fresh elevation. We have observed more that one case at Guy's Hospital in which similar strange deviations in the regular course of the fever took place again and again, and, in fact, made up the greater part of the temperature chart, without any explanation being found.

The *pulse* may gain in frequency from day to day, but sometimes it remains for several days at 90 or 100, the only change being that it becomes gradually smaller and softer, or even dicrotic in character. In adults there is always ground for alarm if it rises to 120, but in children it may reach 130 to 140 without danger; in old people it is commonly much slower.

The *tongue* is thickly furred in pneumonia; as the disease advances it often becomes dry, brown, and covered with sordes. The bowels are generally constipated, but sometimes there is diarrhœa.

A symptom which usually makes its appearance between the second and the fifth day is an eruption of *herpes* upon the lips or face—a crop of clear painless vesicles occurring in a group on a red patch of skin. It is said to occur in from two fifths to one half of all cases of pneumonia, and to be far more common in cases that do well than in those that end fatally. This has long been a traditional opinion, and it seems to have been established by the observations of Geissler, who found ('Arch. d. Heilkunde,' 1861) that out of 431 cases the mortality among those in which there was no herpes was 29·3 per cent., whereas among those with herpes it was only 9·3 per cent.

After the first few days the *skin* in many cases becomes moist, and there is occasionally profuse sweating. An icteric tinge of the conjunctivæ is not uncommonly present, and sometimes there is well-marked *jaundice* of the skin. Formerly it was taught that this occurred only when the base of the right lung was the seat of the disease, and that it was due to the extension of "the disease" through the diaphragm to the liver-substance—an unscientific conception. The truth is that icterus may appear when pneumonia affects the left lung or the upper lobe of the right. The jaundice would seem to be due either to venous congestion of the liver or to catarrh of the common bile-duct accidentally present as a complication.

The *urine* in pneumonia is scanty, of high specific gravity, high-coloured, and strongly acid, depositing lithates in abundance. The amount of *chlorides* excreted by the kidneys undergoes a great diminution; they may even be altogether absent. At one time this was thought to be of great diagnostic

importance. But the same thing occurs more or less in other febrile diseases, the explanation being apparently that the salts in question are retained in the body, for, as Cohnheim argues, the diminished supply of them in the food is insufficient to account for so great a difference. During convalescence they reappear, probably in increased quantity. Not infrequently the urine contains *albumen*. This probably happens in from a fourth to a third of the cases. It is not of ill prognosis, and never leads to Bright's disease.

The *nervous system* is, as a rule, less affected in pneumonia than in other maladies with equally high temperatures. Many patients retain their consciousness throughout the whole of the illness, or merely wander a little at night during their broken sleep. But in other cases *delirium* appears as the fever increases, and it may be a furious maniacal type. In persons who have been intemperate, pneumonia is often attended with symptoms exactly like those of delirium tremens, or, to put it in another way, that affection may be present as a complication. An inherited neurotic tendency seems also to lead to the occurrence of severe cerebral symptoms in pneumonia. In the case of a man whose last hours were passed in a paroxysm of raging madness the author was told that hardly one of the brothers and sisters of the patient had escaped some form of neurosis. Pneumonia of the apex is particularly apt to cause delirium, or in children convulsions.

Modes of death.—The symptoms which precede death are generally the same. The breathing becomes more and more rapid, but shallow and ineffectual, the patient being no longer conscious of the necessity for filling his lungs. He sinks down in bed away from the pillows on which he was propped; the face is pale and livid in hue, leaden or slate-coloured; the skin is covered with a cold sweat; the pulse becomes weak, irregular, and finally imperceptible. Occasionally death is sudden, from the heart failing during some effort, as when the patient raises himself up in bed. Lastly, it now and then happens that the occurrence of the crisis (to be described in the next paragraph) is followed by prostration and collapse, from which the patient never rallies.

Defervescence.—In cases of pneumonia that end in recovery, the subsidence of the pyrexia and of the other symptoms is usually abrupt, *by crisis* (p. 30). In about 65 per cent. of cases, in which the exact duration of the disease can be reckoned from an initial rigor, or convulsion, or vomiting, the crisis is found to occur between the fifth and the eighth days: next often on the sixth, or the seventh. In some cases it is earlier; in others it is delayed until the second week. It is rare for fever to continue longer than this; and when defervescence fails to occur by the fourteenth day there is ground for suspicion either that the case is not one of true pneumonia, or else that some complication is present.

The crisis usually begins in the evening or night, scarcely ever in the forenoon. The fall of the temperature is as a rule rapid, being completed in about sixteen hours, and sometimes in five or six; but in some cases twenty-four hours pass before the thermometer reaches 98·5°. For the next day or two it often stands below normal.

Less frequently the defervescence in pneumonia takes place gradually, *by lysis*, and occupies two or three days.

In cases which end by crisis, it is surprising how much better the patient feels as soon as the pyrexia has subsided. His appetite quickly returns, he sleeps well, and his skin perspires comfortably. Both the pulse and the

respiration decline step by step with the temperature. Yet the physical signs may at first fail to indicate any improvement in the state of the affected lung, and several days may pass before the consolidation clears up.

There are no *sequelæ* of pneumonia. The patient may be allowed to eat as his appetite returns, and to go abroad when he feels able to. There is no danger of phthisis or other chronic affections following. In this respect it resembles typhus, and differs widely from enterica, as also from pleurisy and from broncho-pneumonia.

Recurrence.—A person who has once suffered from pneumonia is afterwards more likely to be attacked by the disease. Instances have been recorded in which it has recurred eight, ten, and even more times. Sometimes the same part of the lung is affected on successive occasions, sometimes not. Relapses are not frequent, if by this term we understand the repetition of the morbid process before the patient has completely recovered. But the spread of the disease to the other lung not infrequently comes on in the form of a relapse.

Ætiology.—Pneumonia is met with at all ages, though rare in children under three years old; and in both sexes, though commoner in men than in women. It is met with in all climates and in every race of the human family. Moreover, it is common among brutes. Pleuro-pneumonia is a frequent cause of death in monkeys, horses, and among cattle; it frequently assumes an epizoötic form, and decimates both oxen and sheep.

Different opinions have been expressed as to whether pneumonia is more apt to occur in persons who are strong and healthy, or in those who are weak and delicate. There is no difficulty in finding instances in support of either view, and one cannot help being profoundly impressed by the cases that one now and then sees of vigorous young men carried suddenly off by this disease. Yet these are, after all, exceptions. "Acute pneumonia occurring in a previously young and healthy subject" is more often described than seen, though if we except specific fevers it is probably more often seen as a primary invasion than any other acute inflammation.

If we take the cases of hepatisation of the lung as they occur in the deadhouse, the majority are found to be secondary to cardiac or renal disease, to enteric or other specific fevers, or to wasting maladies like cancer, diabetes, and paraplegia. On the other hand, it is not frequent for acute lobar pneumonia to be associated with phthisis, with bronchitis, or with primary pleurisy.

Even if these cases be excluded, and we examine the records of apparently primary idiopathic pneumonia, we find, as Dr Wilks has long taught, that in many cases the patient is old and feeble, or half starved, or habitually intemperate.

Occasionally pneumonia assumes an *epidemic* character among men, as among cattle. This is seldom seen now, but there is reason to believe that, like measles, syphilis, influenza, and perhaps the sweating sickness, it was once a more frequent type, and that its present sporadic occurrence has not been, and possibly may not be, always the rule.

In Dr Sturges' interesting monograph there are accounts of epidemic and very fatal pneumonia in Flanders during 1557, in the garrison of Philipsbourg in 1688, and in Iceland in 1863. He also refers to an epidemic in the 22nd Regiment, when stationed in New Brunswick, recorded by Dr Walshe in the 'Army Medical Reports' for 1867, and to one in the Mediterranean Fleet in 1860, described by Dr Bryson in the 'Lancet' (Jan.

9th, 1864). Jürgensen recorded the prevalence of epidemic pneumonia from 1873 to 1881 in the village of Lustnau, near Tübingen, and Dr Ballard reported to the Local Government Board an outbreak of apparently infectious pneumonia at Middlesbrough in 1888.*

Cases have been reported of *infectious* pneumonia. One striking instance of five adult brothers and sisters, living in the same house and successively carried off by the disease, was described by Dr Patchett in the 'Lancet' for 1882. It had occurred in 1876.

The principal exciting cause of pneumonia—as of pleurisy and bronchitis—is commonly supposed to be "catching cold." There is no physician who cannot recall to his memory instances in which patients were attacked immediately after getting wet through, or after lying on damp grass, or after some other very definite exposure to cold. But writers who have tabulated their cases, with the object of determining the frequency of the operation of cold as a cause of the disease, have failed to trace it in any but a comparatively small proportion. Among 205 cases collected by Grisolle, 45 were supposed to be due to cold; but among 186 cases of Ziemssen's only 10, and among 212 cases of Griesinger's only 4, could be clearly attributed to this cause.†

Again, in the relations of pneumonia and of bronchitis respectively to different climates and to different seasons of the year, there are differences which oppose the view that the two diseases have the same ætiology. Pneumonia does not, like bronchitis, increase in frequency with the latitude from the equator towards the poles. And with respect to the various seasons of the year, observations made at Vienna have shown that whereas in that city the prevalence of bronchitis reaches its maximum in March, and then gradually declines through the rest of the spring and summer, the prevalence of pneumonia increases steadily from February to May, after which it falls rapidly. This last part of the statement must not be taken as applying to other places besides Vienna, still less to Europe generally; for Jürgensen finds that there is a broad difference between continental and insular climates as regards the months in which pneumonia is most apt to occur; in the former it is between March and May, in the latter between December and February. But if the year be divided into two halves, the one from December to May, the other from June to November, then it is found that, throughout Europe, two thirds of the cases of pneumonia fall into the first half, one third into the second.

Another point which confirms the opinion that pneumonia is not directly due to cold is that sailors and others whose occupations expose them to bad weather do not seem especially prone to the disease.

Again, true pneumonia is not set up by local *injuries* to the chest, wounds of the lungs, foreign bodies in the bronchi, or any like causes. Traumatic inflammation of the pulmonary tissue is chronic and interstitial, or may be acute and caseous, but it is not hepatisation. It is impossible to induce the affection experimentally in animals.‡

In the pneumonic lung, as in so many other morbid structures, the

* See the bibliography by Dr Coupland in the Report on Acute Pneumonia ('Collective Investigation Record,' vol. ii, p. 10); also four instances, *ibid.*, vol. i, p. 104, and a full account of an epidemic of pneumonia in the Punjab by Surgeon-Major Maunsell, vol. ii, p. 77.

† These figures are taken from Jürgensen's article in 'Ziemssen's Handbuch.'

‡ Sommerbrodt stated that he saw it follow the injection of a solution of perchloride of iron into the air-passages; but Jürgensen repeated the experiment, and the result was negative.

discovery of microphytes has rewarded the diligence and skill of modern histologists. Friedländer first described in 1882 micrococci, usually occurring in pairs or chains, and surrounded by an envelope (*Diplococcus pneumoniæ*). They are frequently present in the hepatised lung, and have been found in the rusty sputum. Dr Giles found them in India ('Brit. Med. Journ.,' July 7th, 1883). But they may also occur in lobular and other kinds of inflammation of the lung. Moreover, other microphytes, spherical and rod-shaped, have been found in cases of pneumonia.

Pathology.—The traditional view is that pneumonia is an acute inflammation of the lung, and that the pyrexia and other symptoms are secondary to the local lesion. For many years, however, doubts have been expressed as to whether this is the true pathology of this remarkable disease; and it is possible to regard pneumonia as a general and specific disease to which the hepatised lung bears the same relation as the intestinal ulcers to enteric fever, or the angina to scarlatina. The following considerations bear upon this question, which is far from having only a speculative interest.

Are we right in assuming hepatisation to be an inflammatory process at all? We have seen that it cannot be caused by injury or irritants, and it is doubtful whether it is the direct result of exposure to cold. It does not lead to suppuration on the one hand or to fibroid induration on the other. The exudation is peculiar, and unlike that of undoubted inflammation which has extended from the bronchial tubes to the air-vesicles. The distribution is remarkable. The disease never or scarcely ever assumes a chronic course.

On the other hand, the inflammatory nature of the process seems witnessed to by the constantly concomitant pleurisy and occasional pericarditis; as also by the exudation of fibrin and leucocytes along with blood-discs. Moreover, we are familiar with other cases of non-traumatic inflammations which are more or less peculiar to the organs they affect, and which, as they do not originate from ordinary irritants, so fail to produce the ordinary results of inflammation. Such are the tubal nephritis of Bright's disease, the membranous laryngitis of diphtheria, and the synovitis of rheumatism.

If the characteristic lesion of pneumonia may be accepted as a special form of inflammation, it is not to the catarrhal inflammation of mucous, but to the plastic inflammation of serous membranes that it should be compared. The pulmonary alveoli are lined by endothelium with lymphatic stomata, not by columnar epithelium with a vascular mucosa; and this is in all likelihood developed from the mesoderm, like the pleuro-peritoneal endothelium, and not like that of the bronchial tubes, from an outgrowth of the hypoblast. The alveoli, not the "parenchyma of the lung," are the primary seat of the exudation of pneumonia, as Addison proved fifty years ago.

If the other symptoms of pneumonia are secondary to the pulmonary lesion, why is the temperature so much higher than in other inflammations, whether serous, mucous, or visceral—higher than in any other disease except specific fevers, tuberculosis, or pyæmia? Why is there albuminuria with cloudy swelling of the renal epithelium, which disappears with the pyrexia, and never leads to permanent local changes? Why are the chlorides so remarkably deficient in the urine? Why do the general symptoms sometimes precede evidence of the local lesion.*

* It has been asked why the general symptoms are so independent of the severity and extent of the local lesion. But its "severity" is probably the same, or nearly so, in every case, and its extent is certainly not without influence; double pneumonia is a more serious disease than single, and consolidation of three fourths of a lung than of half its lower lobe.

Again, the course is said to be too typical for that of a local inflammation. Why does crisis often occur at the end of a week, and why is convalescence so rapid and complete?

Pneumonia, though certainly not infectious in the ordinary sense of the term, sometimes occurs, as we have seen, in epidemics; yet it does not protect from future attacks.

Lastly, the presence of a microphyte, even if not yet ascertained to be constant and characteristic, suggests a specific origin and character.

In the first edition of the present work the author regarded as not disproved the common opinion that pneumonia is essentially a local inflammation, accompanied by symptomatic pyrexia. "The truth," he remarked, "seems to be that the question of the real pathology of pneumonia is involved in a much wider one, to which at present no positive answer can be given. We have seen, in the chapter on inflammation, that many modern observers believe that no form of spreading inflammation is due merely to the reaction of the organism against a local injury. If this be the case, some specific exciting cause, such as Jürgensen assumes for pneumonia, must be supposed to be present in a vast number of other inflammatory diseases. Probably many years will pass before the true relations of all of them are fully understood. In the meantime it would not be really advancing in the right direction to detach pneumonia from other thoracic affections, with some of which it may, after all, prove to be closely allied, or to force it into a close relation with the group of acute specific diseases as now understood, from which it certainly differs in many important particulars." It appears to the present writer that the evidence tends to show that pneumonia is neither a specific fever nor a mere local inflammation, but the special idiopathic disease of the lung, like acute nephritis and acute yellow atrophy of the liver. Much depends on the view taken of the pathology of inflammation generally, and on the validity of the distinction between acute pneumonia and other forms of inflammation of the lung.

Prognosis.—Uncomplicated pneumonia is far less dangerous than its severe symptoms seem to threaten. The average death-rate cannot be stated with accuracy; for, in the first place, it varies enormously, according to the number of primary cases in proportion to those which are secondary to some other disease; many of the latter are obviously hopeless from the first. Moreover, the danger of pneumonia is widely different at different ages—children as a rule recover from acute lobar pneumonia; and in young healthy adults, of temperate habits, the prognosis is almost as good; Jürgensen gives the death-rate in such cases as from 3 to 6 per cent. But to old people, *i. e.* to all above sixty—or to those who, though not old, are worn out by misery, dissipation, or drink*—the disease is exceedingly fatal. Nevertheless, from time to time one sees a patient recover even when the circumstances have appeared most adverse.

The most important considerations as to the prognosis in a case of pneumonia—apart from the age of the patient (which is almost as important as in typhus or in diabetes) and his habits—are the presence of renal disease and the presence of heart disease; either of these complications makes even a limited consolidation of a single lung in a young and temperate person of the gravest significance.

* Of 37 cases of pneumonia in persons reported as intemperate, 15 died, or about 2 in 5; of 228 reported "temperate," 42 died, or less than 1 in 5; and of 80 total abstainers, 9 died, or little over 1 in 10 ('Collective Investigation Record,' vol. i, p. 95). The third class would include a large proportion of children, and the first many elderly people.

Lastly, even in a young and healthy subject, danger is indicated if the local lesions are extensive, if the whole of one lung or if both lungs are affected. Experience has taught that it is never safe to speak confidently of the recovery of a patient with pneumonia, however favourable its course may be during the first few days. For what was single may soon become double pneumonia; a change for the worst is apt to occur suddenly; the pulse, of moderate frequency hitherto, runs up quickly, respiration becomes more frequent and shallow, the strength fails with terrible rapidity, and in a few hours the end may come. In all probability the cause of the fatal issue in such cases is the supervention of inflammatory œdema or "acute congestion" in parts of the lungs previously unaffected. Other cases go steadily downwards from the very commencement.

In children above infancy, primary lobar pneumonia is of good prognosis. But the less apparently severe cases which appear in rachitic children, or after measles and whooping-cough, and perhaps are really catarrhal pneumonia affecting a number of lobules close together, are more dangerous, particularly in children under three years old. Of 120 cases of lobar pneumonia in children Dr Goodhart lost 25.

Treatment.—Pneumonia has been the battle-field of therapeutics as well as of pathology, since it was described clinically by Laennec and anatomically by Rokitansky.

From 1820 to 1840 antiphlogistic treatment was vigorously applied to this, the typically sthenic inflammation in a young and healthy subject. In France especially *la saignée coup sur coup* was practised in the hope and belief of "jugulating" the disease. In England twenty ounces of blood and more were often abstracted from the arm, time after time, or the patient was bled in the recumbent posture, so as to obtain a larger flow before syncope occurred. Any failure was ascribed to want of early and bold venesection.*

Mercury, usually in the form of calomel, and combined with opium, was also given as a necessary adjunct to venesection, particularly in England. Antimony was often conjoined with mercurials, and in Italy it was given in large and nauseating doses as a specific remedy for pneumonia.

A great revulsion of practice occurred in this country in the fifth and sixth decades of the century against "antiphlogistic" and in favour of "corroborant" treatment of inflammations, and of acute diseases generally. Wine and brandy, often in "heroic" doses, were prescribed in pneumonia under the influence of the late Dr Todd.

Meantime, some physicians, among whom the late Dr Hughes Bennett, of Edinburgh, deserves the foremost place, had been observing the natural history of pneumonia, and had found that, at least in young and temperate patients, its danger had been much over-estimated, that it tended to recovery after a week's duration, and that neither bleeding, nor mercury, nor antimony nor alcohol was necessary in favourable cases, or could be depended on to save life in unfavourable ones. For many years past the treatment of pneumonia in England has been practically the same as that of typhus, enteric fever,

* In Germany Skoda, then at the head of the Viennese school, had learned to distrust large and systematic depletion, although he still bled in the earlier stages of pneumonia, and believed in the power of drugs to defibrinate the blood and cut short the disease. There was a remarkable contrast between the treatment of pneumonia in his wards, as witnessed by the writer in the year 1865, and in those of Bouillaud during the preceding winter, where repeated bleeding was still the rule. At the same time cases of pneumonia were being "cured" at the Homœopathic Hospital in Vienna by infinitesimal doses of useless drugs.

or scarlatina—expectant, not in the sense of doing nothing for the patient, but of putting him in the best circumstances for recovery when the malady has run its course, and watching meantime for any unfavourable symptom, so as to meet it when it appears.

Of late, however, it has been asserted by some German physicians that better results can be obtained by vigorous antipyretic treatment, like that which has been described in the chapter on enteric fever. At Basle cold baths have been used whenever the temperature rose a little above 102° Fahr. Jürgensen advises that 104° should be the point at which baths should be systematically employed; while for patients whose temperature ranges at from 101° to 103° he merely orders a tepid bath in the morning, so as to increase the normal remission during the early part of the day. He also administers quinine in doses of thirty grains at intervals of forty-eight hours. The theoretical basis of this practice is that the great danger of pneumonia is failure of the heart, as the result of the combined action of pyrexia and of disturbance of the pulmonary circulation. In proof of its efficacy Jürgensen adduces a tabulated statement of the fatal cases that have occurred in his practice, showing that scarcely any of his patients died except such as had some dangerous complication. He makes a point of giving wine as a stimulant to the heart before each cold bath; and when signs of cardiac failure appear, he gives alcohol freely, as well as camphor and musk.

Few English physicians, however, believe that pneumonia can be jugulated by cold baths any more than by bleeding, or that moderate pyrexia is so injurious that it must be persistently attacked.

Even if cold baths are harmless, there is reason to believe that antipyretic drugs are as liable to do mischief as the antiphlogistic treatment which they now supersede. A careful trial of antipyrrhin in a series of cases of acute pneumonia led the late Dr Botkin, of St Petersburg, to the candid avowal that it was doubtful if it ever did good, and certain that it often did harm.

The present writer has more than once employed venesection in what seemed a suitable case without preventing death, has used cold baths to check pyrexia without doing any harm, but with doubtful effect on the course of the disease, has given aconite from the beginning without in the least altering the rise of temperature or averting serious complications, and has seen quinine, antimony, wine, and brandy, all in turn prove useless to check the progress of the disease.

The non-specific and rationally expectant treatment of pneumonia, as generally carried on in hospitals and in private practice in London, is somewhat as follows.

On the first rigor and rise in temperature the patient is put to bed, kept undisturbed, and his strength husbanded. The worst cases are those in which the patient has kept up during the first day of illness, or when some unhappy street outcast has walked about with the disease upon him until brought exhausted to a hospital.

The room must be kept comfortably warm. The patient must not talk, and must not sit up in bed. A single calomel purge does no harm, and has the advantage of preventing the exhibition of physic afterwards, when the patient is less able to bear its effects.

The diet should consist of beef-tea, milk, and arrowroot or gruel, with tea, fruit, jelly or ice, if desired, and a free supply of water, effervescing

drinks, or any harmless form of diluent. A cup of tea is harmless and refreshing, and strong coffee is sometimes a useful stimulant. Nitre, citrate of potash, or acetate of ammonia are usually prescribed, and probably are of real service as diuretics, and by promoting the solution and excretion of inflammatory products towards the close of the disease; but they need not be insisted on if (even when suitably disguised) they are refused by a child.

When pleuritic pain is present it may often be relieved by poultices, a mustard plaster, or, according to some authorities, by a blister; but in really severe pain nothing gives so rapid and complete relief as a few leeches. In aged or feeble patients we must trust to hot applications and morphia injections.

When cough and expectoration are difficult, ipecacuanha with paregoric and squills is indicated. If there is continued want of sleep, ten grains of Dover's powder is probably the most efficient remedy, and mere symptomatic albuminuria does not counter-indicate it. If, however, there is any doubt as to the efficiency of the kidneys, it is safer to give chloral hydrate or hyoscyamine.

If the temperature rises over 104° in the case of an adult, cold sponging should be employed, and if this is ineffectual and delirium is present, Leiter's coils, or the wet pack or ice-bags under the armpits are probably safer than the cold bath. Nevertheless, if the heart is sound and the patient young, a bath may be used. Dr Lees has lately published some good results of treatment with ice-bags ('Lancet,' ii, 1889), and Dr Goodhart has recorded his own experience of the treatment of pneumonia by cold applications in the 'Guy's Hospital Reports' for the same year.

If cyanosis appears, with signs of dilatation of the right side of the heart —a small, frequent, and feeble pulse, epigastric pulsation, distended and pulsating jugular veins—the abstraction of six, eight, or even ten ounces of blood from the arm will relieve the pressing symptoms and perhaps do permanent good. Wet or dry cupping between the shoulders is generally less effectual.

In the case of children, writes Dr Eustace Smith, where there is great dyspnœa and threatened cardiac failure from over-distension of the right side of the heart, life may often be saved by taking one, two, or more ounces of blood from the arm, according to the age of the patient. "I can look back," he continues, "to some fatal cases which I now believe might have been saved had I had the courage to relieve the labouring heart by judicious removal of blood."

The greatest danger in pneumonia is not from the fever nor from the pulmonary obstruction—it is from failure of the heart. To meet this, digitalis may be given with advantage, but it is less effectual than in cases of valvular disease. Ammonia, with or without senega, ether, and Hoffmann's anodyne (Sp. Ætheris co.) are all valuable drugs. But the most important means of meeting either an obstructed pulmonary circulation or a directly failing left ventricle is to use brandy frequently and in measured doses, but increased if necessary up to twelve, fifteen, or twenty ounces in the day. Children and young adults seldom need it, but there are few patients above forty, and probably none above fifty, who do not need stimulants in larger or smaller quantities from very early in the disease. Sometimes port wine or champagne suits better than brandy; the kind of stimulant may be decided by the patient's feelings, but the quantity and

frequency must depend on the state of the pulse and the first sound of the heart.

Secondary forms of pneumonia.—We have seen how the course of pneumonia differs according to the age and habits of the patient, and according as the heart and the kidneys are healthy or the reverse. Another important practical distinction is between primary pneumonia, with or without complications, and pneumonia secondary to other diseases.

In *rheumatic fever* pneumonia is not common, but when it occurs it is a very grave complication.

In the course of *Bright's disease*, particularly in the parenchymatous and lardaceous forms, pneumonia is almost always fatal.

In *disease of the heart* it commonly attends pulmonary hæmorrhage (or "apoplexy," as it has been called), a condition in which the air-vesicles are filled with blood, and a patch of lung becomes solid, dark red on section, and like damson-cheese in appearance. Hepatisation often takes place around the wedge-shaped mass of solid lung, but it does not spread far, and the symptoms are not so severe as those of primary pneumonia.

In typhus, enterica, and other *fevers* ordinary lobar pneumonia may occur (pp. 112, 129, 148); but far more frequently a condition of the lungs is recognised during life, and verified after death, which has been called "typhoid pneumonia," or, more properly, "*hypostatic pneumonia with congestion.*" It is found occupying not the bases, but the backs of the lungs—the lowest part as the patient lies in bed; it almost always affects both lungs more or less; it is not continuous, but consists of patches of airless tissue, including several lobules, and surrounded by congested and œdematous but crepitant lung (cf. pp. 111, 144). It is not accompanied by the high temperature of primary pneumonia nor by its other striking characters, and yields imperfect resonance rather than dulness, toneless or subcrepitant râles rather than true pneumonic crepitation. When recognised, it shows prostration in general, and weakness of the cardiac muscle in particular, and calls for ammonia and for brandy.*

Alcoholic pneumonia, or that which is found associated with delirium tremens, has been already mentioned (p. 994).

Inflammatory œdema and acute pulmonary congestion.—Dropsy of the lung is not infrequent in the course of Bright's disease; as with œdema of the glottis, it is probably always in some degree inflammatory. But apart from these cases there is an œdematous inflammation of the lungs which comes on acutely and without previous disease. It has been described as acute pulmonary congestion, and may or may not be identical with the first stage of hepatisation (p. 986). A case is narrated by Hertz in 'Ziemssen's Handbuch,' and another by Dr Leuf in the 'American Journal of Medical Science,' January, 1885. Such marked and severe cases are rare, but many intelligent observers believe that "active congestion" of the lungs, distinct from pneumonia and from phthisis, is a real and not infrequent malady.†

Chronic lobar pneumonia.—We have seen that one peculiarity of acute pneumonia is that, when the patient recovers, the hepatised lung clears up completely, and the tissue retains no trace of injury from the severe per-

* It is in this sense of hypostatic congestion that Arbuthnot's dictum applies: "A peripneumony is the last fatal symptom of every disease, for nobody dies without a stagnation of the blood in the lungs" ('Of Diet,' chap. iii).

† See on this subject Hodgkin's remarks ('Lectures on Morbid Anatomy,' vol. ii, p. 129).

version of structure it has passed through. But to this, as to every pathological rule, there are occasional exceptions. Abscess following pneumonia is so rare that its very existence is doubtful (p. 987); gangrene only ensues under special conditions, which will be discussed further on; and phthisis does not originate in acute lobar pneumonia.

But Addison described certain rare and exceptional cases in which, after an illness of a few weeks, with all the evidences of consolidation present, the patient dies, and the lung is found uniformly "albuminised." The section is not soft, lacerable, and granular, as in acute grey hepatisation, but smooth, solid, and tough. The alveoli are full of fibrillated lymph, and the exudation cells may have begun to be granular and fatty. It is a condition of the lung very liable to break down, and thus lead to rapid phthisis; on the other hand, it is a condition from which recovery may take place, and the lung be completely restored.

Wilks and Moxon, after quoting this account, continue, "That there is a chronic pneumonia of such a kind can scarcely be denied when it is remembered for how long a time all the signs of consolidation may endure, and then a complete restoration take place. We must therefore believe that there is a true chronic pneumonia, whose origin is an ordinary inflammation and exudation into the alveoli, and whose appearance is best denoted by the term 'uniform albuminous induration.'"*

They add, however, that such chronic pneumonia may be of the lobular kind, and Addison himself said that this condition may be limited to one or a few lobules only; so that it may perhaps be doubted whether this "least frequent of the permanent pneumonic indurations of the lung" is not, after all, an unusually extensive catarrhal pneumonia.

BRONCHO-PNEUMONIA.†—In children, acute bronchitis affecting the smaller bronchial tubes is often accompanied by inflammation of the pulmonary alveoli, usually of both lungs. And even in adults the same thing is observed, although very rarely. Among children it is especially at an early age that this is apt to occur. Ziemssen, out of ninety-eight cases, found that sixty-seven—and Steffen, out of seventy-two-cases, found that fifty-two—occurred in patients under three years old.

Ætiology.—In many instances the affection is secondary to some infective disease. Measles and whooping-cough furnish by far the largest number of cases of broncho-pneumonia. It is also sometimes seen after diphtheria, rubeola, smallpox, or scarlet fever. Jürgensen insists, as other writers had before, on the greatly increased liability to broncho-pneumonia, as a complication of bronchitis (whether after measles or independently of any infective disease), in those who are obliged to breathe impure air in the close, narrow rooms of the poor. He is even disposed to attribute the greater frequency of the affection in winter to defect of ventilation rather than directly to inclemency of season. It is probable that rickets renders a child more apt to become affected with broncho-pneumonia if it is attacked with bronchitis. Dr Wilks, in the 'Guy's Hospital Reports' for 1860, showed that broncho-pneumonia is a common cause of death in children suffering from severe burns.

* 'Pathological Anatomy,' p. 338. Addison's original description appeared in the 'Guy's Hospital Reports' for 1843, and will be found in the volume of his collected papers published by the New Sydenham Society, p. 27.

† *Syn.*—Catarrhal pneumonia, Lobular pneumonia, Pulmonary or Alveolar catarrh.

As to the special causes of the exceptional cases when broncho-pneumonia like that of infants occurs in adults, it is at present difficult to say anything definite. The following are a few cases which occurred at Guy's Hospital. A woman, aged thirty, having miscarried eight days before, was attacked with shivering and headache, and died after an illness that lasted ten days. A man, aged twenty-five, of dissipated habits, who was said to have been under a course of mercurial treatment for syphilis, received a blow on the nose while he was drunken; this was followed by epistaxis, which continued until the nares were plugged; the mucous membrane then suppurated profusely, the discharge being very fœtid; and he sank and died at the end of a week. A third case was that of a man aged twenty-eight, a singer at a music-hall. He had a fall from a cart, and this led to an illness which proved fatal in three weeks. At first he tried to go on with his singing, but he was soon obliged to give it up. When admitted, shortly before his death, he was already comatose. In this instance some of the patches showed central sloughs, but in the reports of the two other cases it is expressly stated that the appearances were identical with those that are commonly seen in children. It seems probable that in the second case the inflammation was set up by the inhalation of fœtid pus from the nasal cavities into the air-passages. Indeed, the report of another case, in which a similar affection of the lungs was met with as a complication of tubercular meningitis in a woman aged thirty-four, attributes broncho-pneumonia to the entrance of food into the bronchial tubes while she was struggling in her delirium.

Breathing irritant gases, especially chlorine in large quantity, sometimes sets up intense broncho-pneumonia. It is not improbable that the immediate cause of the ordinary broncho-pneumonia of children is often, if not always, the entrance into the alveoli of inflammatory products formed in the smaller tubes, as the result of violent inspiratory efforts.

It is also said that broncho-pneumonia is not infrequent in extreme old age, and that it often ends the life of those who have long laboured under senile bronchial catarrh.

Anatomy.—The most obvious indication that pneumonic consolidation in a given case has arisen by extension from the bronchial tubes is its occurring in scattered patches throughout the lungs. These patches are more or less rounded in form; they are usually of about the size of peas, but sometimes may be larger. They are reddish brown in colour, or more or less grey, or greyish yellow, according to the stage to which the inflammation has advanced. As seen upon the cut surface of the lung, they appear slightly raised above the rest of the parenchyma. They have a dull, lustreless appearance, and are granular on section, but the granulations are less obvious than in the red hepatisation of genuine acute pneumonia. The substance of the patches is soft and friable, and when squeezed they emit a more or less opaque fluid. They are sometimes so closely collected together in part of a lung that a whole lobe may seem to be consolidated. Even then, however, the lobular markings are usually distinct, and the cut surface has not that even and uniform appearance which characterises true lobar hepatisation. Many lobules are found collapsed and others dilated.

More or less pleurisy is very commonly associated with broncho-pneumonia, there being a thin layer of lymph upon the pleural surface, especially over any patches that happen to lie just beneath the serous membrane. Indeed, both at the bedside and in the deadhouse it is a remarkable fact

that, altogether apart from the presence of any obvious pneumonia, pleurisy is a far more frequent complication of bronchitis than one would have anticipated: in adults affected with bronchial inflammation a pleuritic friction-sound may often be detected if it is listened for.

Histologically, the morbid process in broncho-pneumonia is a *catarrhal* inflammation; that is to say, the cells which fill the affected alveoli are many of them epithelial in character, large, of irregular shapes, with bold nuclei. With them are found leucocytes and mucus, but neither blood-discs nor fibrin. Probably the seat of the disease is the intra-lobular air-passages, and the contents of the vesicles are derived from the former source.

In some cases the inflammation appears to spread to the connective tissue by which the pulmonary lobules are united together. Jürgensen speaks of "thick whitish-grey bands, which are seen crossing one another upon the cut surface of the organ." In 1878 a well-marked instance of this occurred in a child, aged three, who died after an illness of five weeks' duration, which perhaps began in whooping-cough. The left lung contained many patches of broncho-pneumonia. The right lung was almost entirely consolidated. Its tissue, however, felt hard; and the fibrous tissue in it had obviously undergone a great increase. Such cases seem to suggest an explanation of an appearance which one not infrequently sees in making autopsies of persons at all periods of life, namely, marbling of a part or the whole of a lung by fibrous bands which intersect one another and divide it up into irregular areas. Such an affection is commonly regarded as indicating early cirrhosis of the organ. But it does not look like a progressive lesion, and is far more likely to be a residue of a former attack of inflammation. Acute lobar pneumonia appears never to cause this appearance.

Clinical course.—The recognition of broncho-pneumonia, in addition to the acute bronchitis which precedes and gives origin to it, is usually more or less uncertain. Physical examination of the chest often helps but little. If several lobules side by side beneath the pleura are consolidated, there may be impairment of resonance (or even dulness) on percussion, bronchial breathing and bronchophony, the latter being especially obvious when the patient, if a child, is crying. Moreover, the bronchitic râles often become clear and "consonating" in quality. Jürgensen lays stress on the occurrence of a crepitating râle like that heard in acute pneumonia, but less fine, and audible during expiration as well as inspiration.

Nor, again, is broncho-pneumonia attended by very marked symptoms. Ziemssen has rightly laid stress on the importance of a sudden rise of temperature, as an indication of its supervention in the course of acute bronchitis, if the pyrexia should previously have been moderate. But, as already stated, the thermometer may indicate 104° or even higher in a child affected with bronchitis, independently of any complication (p. 957). Jürgensen says that broncho-pneumonia—as, for example, after measles—may be accompanied with a temperature of 105·8° for days together, with scarcely any remissions. In fatal cases the temperature sometimes rises before death, reaching perhaps 107° or 108°; sometimes it falls below normal. The pulse is often extremely rapid, so that it cannot be counted at the wrist. In children a pulse rate of 150 to 200 is by no means incompatible with subsequent recovery; so that it must not lead one to give an absolutely fatal prognosis. It is surprising, too, how hurried the breathing may be in cases which yet do perfectly well. What is really alarming is for the pulse to be feeble and "running" from emptiness of the arteries. When the

disease ends in recovery, the pyrexia and the other symptoms gradually subside (*lysis*); there is never a sudden fall of temperature (*crisis*).

Herpes on the lips seldom accompanies this affection. Albuminuria and diarrhœa are not infrequent. As regards what may be termed chest-symptoms, it often happens that with the supervention of broncho-pneumonia the cough from which the patient had been suffering ceases, or becomes less loud and shorter in character. Usually no expectoration makes its appearance. There is generally extreme restlessness, the child tossing about in bed, and asking to be taken up by its nurse and shifted in position every few minutes. The breathing is often shallow. The face and the lips are apt to become pale, with perhaps a livid blush upon the cheeks. There is on the whole more dyspnœa and distress than in cases of lobar pneumonia.

Diagnosis.—One point, of great clinical importance, is that broncho-pneumonia sometimes gives rise to cerebral symptoms of so prominent a character that one may easily suppose the case to be one of *tubercular meningitis*. Delirium, coma, retraction of the occiput, vomiting, strabismus, convulsions, may all appear in turn. Jürgensen makes the formal statement that, in a child affected with broncho-pneumonia, it may be absolutely impossible to say with certainty whether these symptoms are due to tubercles present in the brain. Of course the question is then whether the pulmonary affection is not really *acute tuberculosis*; and, apart from nervous symptoms, this is often difficult to decide.

Broncho-pneumonia in children may be mistaken for *enteric fever*. Rose spots are far from constant in children; diarrhœa is frequent in broncho-pneumonia, and often absent in enterica; but a full abdomen and a swollen spleen point to the latter, and the curve of temperature, with its relation to the respiration, will generally decide the question.

Prognosis.—The ordinary duration of broncho-pneumonia is about a fortnight; but sometimes it runs on for three or four weeks or even longer. It may destroy life very rapidly—within a few days, or even in twenty-four hours. Sometimes the cause of death seems to be marasmus, all acute symptoms having passed off. Jürgensen gives some figures from which it appears that the disease is fatal in from half to two thirds of the cases. When consecutive to measles the risk is said to be smaller than this. Convulsions are of bad omen. Very young infants are far more likely to die than older children; and the prognosis is also more serious in those who are weakly, rachitic, or very fat. In children it is far more dangerous a disease than lobar pneumonia. Of forty-five cases of acute lobular broncho-pneumonia in children, recorded by Dr Goodhart, twenty were fatal. He notes the frequency with which, when one lung is inflamed in a child, the other shows signs of the same process here and there in a partial and often transient form.

Treatment.—Emetics do good service in the first few days; afterwards they are too depressing. Expectorants are useful, but opium must be avoided. The ammonia and senega mixture is almost always valuable; and sweetened with glycerine or treacle or syrup of tolu it will be taken by children as well as other medicines. Counter-irritation is often useful, and mustard poultices are well borne by the skin of even young children. Dr Eustace Smith recommends dry cupping of the back in bad cases. Diarrhœa should be checked by chalk powder. Stimulants are almost always necessary—sweetened brandy and water, rum and milk, or the egg-and-brandy mixture.

During convalescence, which is often long and tedious—contrasting with

that of lobar pneumonia—quinine and iron are indicated, with cod-liver oil; and it is desirable to remove the child to the sea-side as soon as practicable.

Vesicular pneumonia is a name used by Stokes, and applies to the first stage of broncho-pneumonia. Usually, in all probability, it soon becomes lobular, but occasionally it may be seen after death as a series of minute dots over the cut surface of a lung, too small for lobules, though too large for single vesicles, and these are found to contain catarrhal products. The same appearance to the naked eye may be produced by cross-section of small bronchial tubes, each surrounded with peribronchial inflammation.

When catarrhal or lobular broncho-pneumonia becomes chronic, the products are apt to undergo *caseous degeneration*. Instead of being removed by expectoration or by disintegration and lymphatic absorption, they remain and set up a spreading alveolar catarrh, which goes on to, but unfortunately rarely ends in, a local tubercular process. This is the ordinary beginning of phthisis, and will be discussed in a future chapter.

The term "lobular pneumonia" is also applied to the suppurative process which attacks the lungs in *pyæmia*. It is lobular in distribution, but its exudation is neither catarrhal, caseous, nor fibrinous, but purulent; and it never occurs except as part of a general process of embolism and septicæmia. The modern doctrine of pyæmia was to a large extent worked out by Virchow and Cohnheim in the case of the pulmonary circulation. When the embolus is non-infective, it produces hæmorrhage by the same mechanism as in the case of the brain; but there is no reason to suppose that this is the only cause of pulmonary apoplexy. Under extreme congestion from obstruction on the left side of the heart the capillaries of the alveoli may give way; or extravasation may occur from changes in the vessels, or in the blood itself, as in cases of purpura hæmorrhagica. When the embolus is infective it produces intense congestion, and soon after suppurative inflammation. The abscesses (or earlier only congested patches) are multiple, and are most numerous in the back part of the lung, and generally near the surface.

The symptoms of this form of lobular pneumonia are merged in those of the fatal disease of which it is part (p. 67), but its presence may be suspected when a case of pyæmia is complicated by pain and other signs of pleurisy, which is caused by an abscess reaching the surface of the lung.

CIRRHOSIS OF THE LUNG.*—This term was first used in 1838 by Sir Dominic Corrigan for an affection of the pulmonary tissue, consisting in a replacement of its alveolar structure by a fibroid material, histologically analogous to that which in the liver causes the disease known as cirrhosis of that organ. Unfortunately, however, the mere presence of such a fibroid material in the lung is far from being characteristic of any one morbid process. The condition which has been termed "fibroid phthisis" is probably, in all but an insignificant minority of cases, nothing but a regressive stage, or a very chronic form, of a really tubercular process. There is reason to believe that the same is also true of the pulmonary diseases which are set up by the inhalation of dust. The question will again come before us when we deal with phthisis and pneumo-coniosis.

There remain cases which are not tubercular, and never have been. One

* *Synonyms.*—Chronic interstitial Pneumonia—Iron-grey Induration of Addison—Induration ardoisée of Cruveilhier—Induration grise et mélanique of Andral—Fibroid lung.

peculiarity that characterises them is that whereas the whole of one lung may be shrunken into a hard grey mass, showing no trace of its proper structure, the other one is perfectly free from any similar morbid process; whereas in phthisis, long before one lung is completely destroyed, the other always becomes involved in the disease. Again, in these cases, when one part of a lung is affected before the rest, it is usually the lower lobe. In each of five cases of double cirrhosis observed at Guy's Hospital the bases of both lungs were found to have undergone cirrhosis; in not a single instance was there any indication of the presence of tubercle, nor were any caseous nodules or masses present. These cases are usually complicated by pleuritic adhesions on the affected side, and often by bronchiectasis.

Anatomy.—The process begins, according to some pathologists, in peribronchitis, which spreads from the smaller tubes to the elastic tissue surrounding the alveoli; according to others, in a chronic inflammation of the subpleural and interlobular connective tissue. Both origins, however, are denied by others, and Wilks and Moxon state decidedly that the process commences in the alveoli and their walls. When fibro-nucleated material occupies the pulmonary structures, and cells and nuclei are found within the alveoli, they refer these cases to double chronic pneumonia. Of cirrhosis affecting one lung only, with thickened pleura and dilated tubes, the same authors say that sections of the lung show not only fibrous tissue surrounding the bronchial tubes and blood-vessels, but also thickening of the alveolar walls. This is well shown in a drawing given by Dr Coats (fig. 231), in which the alveoli are represented as lined with large nucleated epithelioid cells, quite unlike those of the normal lung, a condition also represented in a drawing by Heschl, reproduced in the late Dr Wilson Fox's article in 'Reynolds' System,' p. 765. When the fibroid degeneration has reached its full development, the lung on section exhibits large tracts of white, slate-coloured, black, or marbled iron-grey tissue, which is completely airless, firm, and sometimes of cartilaginous hardness. The microscope shows only dense, white, fibrous tissue, with no trace remaining of the pulmonary structures which it has displaced.

Origin.—This chronic fibroid induration is an important conservative process in phthisis, few cases of which are entirely without some cicatricial induration; but as a process independent of tubercle its pathology is still a matter of uncertainty; possibly it has more than one mode of origin.

(1) Now and again it seems to have begun in an attack of acute lobar *pneumonia.* This question was already touched upon (pp. 988, 1003) when the opinion of Dr Wilks was cited, that acute lobar inflammation of the lung, if it does not prove fatal, always undergoes resolution, and never leads to a chronic induration of the pulmonary tissue. But, after all, the evidence on which this opinion was based must have been of a negative kind, consisting in the observation of a number of cases, in none of which such a result was noted. In hospital practice it can very rarely happen that a patient comes under the eye of the same physician during an acute illness, and again, months or years afterwards, when a chronic affection of the lung proves fatal. Moreover, medical literature contains several carefully recorded cases in which the origin of cirrhosis in pneumonia appears to have been clearly established. The two following are taken from Dr Bastian's collection of thirty cases, tabulated in the second volume of 'Reynolds' System.' The first occurs in Charcot's 'Thèse de Paris.' The patient, a man aged sixty-one, was admitted on March 30th, 1850. He had

been attacked five days before with rigors and pain in the side, and had rusty sputa. There were all the signs of pneumonia affecting the whole of the right lung. These continued with but little alteration until his death on July 19th. At the autopsy the right lung was of a greyish-blue colour on section, as hard as cartilage, shrunken to two thirds its natural size, and enveloped in an immensely thickened fibrous mass. The other case was recorded by Dr Mayne ('Dublin Hosp. Gaz.,' May, 1857). It is that of a man aged fifty-four, who in July, 1855, after a hard day's work, was seized with rigors and all the symptoms of pleuro-pneumonia. The acute disease subsided, but he never afterwards regained his health and strength. In October, 1856, he was attacked with fresh febrile symptoms, and he died at the end of the year. The lung, on *post-mortem* examination, was found affected with well-marked cirrhosis.

Dürr has recorded, in a volume published by Jürgensen, two cases which occurred in very young children. In each of these the primary attack appeared to be one of lobar, not catarrhal, pneumonia. Probably, however, the "pneumonia" which leads to cirrhosis is as a rule lobular and catarrhal, and in children it is often secondary to measles or whooping-cough.

To this origin in alveolar catarrh Dr Fagge was disposed to refer one variety of the affection, in which, instead of the tissue of any part of the lung being all converted into a fibrous substance, it is marbled or intersected by bands crossing one another, so as to split it up into areas of various sizes and shapes. The clinical significance of this appearance, which is not uncommonly seen in the deadhouse, is not known. It is generally supposed to represent an early stage of cirrhosis, such as might, if the patient had lived, have involved the whole lung. But may it not be rather a residue or relic of a former acute process?

Many pathologists who find difficulty in admitting the origin of pulmonary cirrhosis in true lobar pneumonia would readily allow the probability of so much more chronic, more irregular, and, so to speak, more irritative a process as lobular or alveolar catarrh, being the antecedent of iron-grey cirrhotic induration.

(2) A frequent concomitant of cirrhosis is *pleurisy*.

In most cases the pleura over the affected part of the lung is adherent to the parietal layer, and the two together form a dense white mass, of cartilaginous hardness and from a quarter of an inch to an inch in thickness. The only way to remove the lung from the chest at the autopsy is to cut it out with the knife. There is also a similar thickening of the pleural layers separating the different lobes. This state of the serous membrane has led to the supposition that the affection began in an attack of pleurisy, and that the lung-substance was invaded from the surface by extension along the interlobular septa. A case showing how easily erroneous conclusions may be drawn, even from *post-mortem* observations, occurred at Guy's Hospital in 1877. A man aged twenty-seven died of disease of the left side of the chest, with a history of having had inflammation of the lungs at the age of fifteen, and some thoracic affection even before that, in early childhood. There was a localised empyema in front, and the pleura elsewhere was thickened in places to the extent of an inch. The lung was very small, but its tissue was generally healthy, except that it was intersected by fibrous bands. It would have been natural to infer that the organ had been invaded from without. But the apex of the other lung was affected in a precisely similar way, although the pleura covering it was in a normal state.

(3) *Dilatation of the bronchial tubes* in the affected lung or part of a lung is present in most cases of cirrhosis.

So intimate, indeed, has been supposed to be the connection between these two morbid conditions, that Grainger Stewart and Jürgensen discuss them together. But various forms of bronchiectasis occur without there being any change in the pulmonary tissue, unless it be emphysema. And in six of Dr Bastian's thirty collected cases of cirrhosis it is expressly stated that the tubes were of their natural size. As to the relation between the bronchial dilatation and the affection of the lung, when they coexist, there are differences of opinion. Some think that a chronic inflammatory process may start from the smaller tubes, and lead to a gradual fibrous thickening of the alveolar walls, with obliteration of their cavities. But the very definite localisation of the morbid process, the completeness of the destruction of the pulmonary texture, and the fact that the pleura becomes so greatly thickened, are arguments against this view. By Corrigan it was suggested that the occurrence of bronchiectasis was secondary to the cirrhosis; he imagined that the contraction of the adventitious fibrous material in the lung dragged upon the walls of the tubes, so as to widen their channels. Dr Wilson Fox, however, seems more likely to be right in thinking that if the dilatation of the tubes really follows the lung affection, it is caused by the expiratory force of a cough, exactly as it is in other circumstances; at an early stage of the disease it is reasonable to suppose that all the affected structures may be soft and yielding.

On the whole, it appears premature to refer the origin of cirrhosis to a starting-point other than the pulmonary alveoli. Many of those cases which cannot be traced to an antecedent pulmonary attack of inflammation, may have arisen from an illness that occurred in childhood and had been forgotten. In others the morbid process may be chronic from its commencement, a true primary chronic inflammation of the lung.

Incidence.—Cirrhosis is most apt to occur in adult men. In Dr Bastian's list there were 24 male and 6 female patients. Two were only seven, 3 were between sixteen and twenty, 21 between twenty-four and fifty-seven, and 4 between sixty-one and seventy-one. In 1887 we had a typical example in Mary Ward, in a boy seven years old.

Symptoms.—As a clinical disease cirrhosis varies according to its extent.

If it affects only a portion of one lung (or even of both), the patient becomes a chronic invalid, with cough, dyspnœa, and most of the other symptoms of phthisis. The expectoration is purulent, sometimes stained with blood, sometimes dirty-grey in colour and offensive; the fingers become clubbed, and there is more or less marked emaciation. The physical signs are those of partial consolidation of the lungs, with the addition of more or less abundant râles. Such cases are not uncommon in hospital practice. After staying a certain number of weeks in the ward, the patient is discharged much as he came in, or at best with some relief to his symptoms. In the five cases of cirrhosis of the bases of both lungs, above referred to (p. 1008), the cause of death was either quite unconnected with the pulmonary affection, or it was an attack of acute pneumonia, or lardaceous disease of the kidneys, the result of the protracted suppuration.

Very different is the course of cirrhosis when it involves the whole of one lung. In that case the affected side of the chest falls in, so that it measures in each direction much less than the other side.

There is often considerable difficulty in distinguishing the disease from chronic pleurisy or emphysema with retraction, after paracentesis. According to Dr Walshe, there is not in cirrhosis the same degree of twisting of the ribs on their axes as in pleurisy, nor is the shoulder lowered so much, nor is the inferior angle of the scapula tilted so far outwards. Great assistance in the diagnosis may be afforded by the discovery of râles on auscultation, and by the presence of abundant purulent, and perhaps offensive, sputum.

From a malignant tumour cirrhosis is commonly distinguished by the state of the mediastinum. This is pushed away by the growth of a tumour, and is dragged over to the farthest possible extent by cirrhosis. If the right lung is cirrhosed, the heart is seen beating at the right nipple; if the left, its visible pulsation may extend upward nearly to the left clavicle. In either case the opposite lung undergoes an extreme degree of enlargement, so that the whole sternal region, and even the space beneath the costal cartilages on the affected side, becomes resonant on percussion, and transmits to the ear a loud vesicular murmur. After a time, however, this over-distended and perhaps hypertrophied lung fails to carry on the respiratory function efficiently. The right side of the heart becomes dilated, a tricuspid regurgitant murmur develops itself at the ensiform cartilage, the patient suffers from permanent orthopnœa, the liver becomes nutmegged, and ascites and œdema of the lower limbs set in. The case, in fact, assumes all the characters of chronic valvular disease of the heart with dropsy, and terminates fatally in the same way.

The *prognosis* of pulmonary cirrhosis is like that of the more chronic cases of phthisis.

Of the *treatment*, all that need be said is that for the relief of the different symptoms such remedies must be used as are recommended for the like symptoms in other diseases, such as phthisis, bronchitis and bronchiectasis, which are more commonly met with in practice.

SYPHILITIC DISEASE OF THE LUNGS.—Only within the last thirty years has it been recognised that other viscera than the testis, and other regions than those accessible to the surgeon's touch, may be seats of syphilitic disease. It is now certain that (apart from the question whether phthisis is ever of syphilitic origin) there is a form of chronic interstitial pneumonia, or cirrhosis of the lungs, characterised by deep scarring and contraction of the tissue, by peribronchitis and tracheitis, often with ulceration and deformity, and by the presence of typical gummata. The process affects the roots or bases rather than the apices; it often starts from previous ulceration of the air-passages; and it is apt to lead to gangrene.

The disease is a rare one, and would be little but a pathological curiosity were it not for the importance of recognising the true pathology of these cases in order to treat them successfully.

Lancereaux described cases of this kind in France ('Traité de la Syphilis,' 1866); Dittrich and Virchow in Germany ('Kr. Geschw.,' ii, 463); and Wilks in this country ('Path. Trans.,' vol. ix, 1858, with plate, and 'Guy's Hosp. Reports' for 1863, 3rd series, vol. ix, p. 33, two cases).

In a series of twenty-two cases of visceral syphilis brought before the Pathological Society in 1877, Dr Greenfield described three of presumably syphilitic affection of the lungs (vol. xxviii, p. 258). In the same volume is the description of a specimen shown by Dr Sutton of chronic syphilitic

pneumonia, from a patient under Dr Gull and Mr Durham in Guy's Hospital (p. 304); three of "fibroid phthisis" in syphilitic patients, by Dr Goodhart, with a histological drawing in which peribronchitis is clearly shown (p. 313, and abstracts of nineteen cases from Guy's Hospital, p. 322); one apparently of gummata coalesced into a large mass in one lung, by Dr Gowers, with a histological drawing (p. 330); one by Dr T. H. Green of a similar large mass in one lung of a man with "undoubtedly syphilitic lesions in his liver;" two by the late Dr Mahomed—both in women with undoubted syphilitic disease, but the pulmonary lesion less certainly of the same origin and perhaps in an early stage; lastly, three of gummata in the lung from the museum at Netley by Dr Aitken.

The following cases have come under the writer's notice:—(1) A woman of about forty at the Hôpital Beaujon in Paris. She was wasted, with cough, purulent expectoration, and hæmoptysis; and from other proofs of lues was treated with perchloride of mercury to her great benefit. (2) A groom of about thirty who, together with signs of chronic pneumonia and hæmoptysis, had tibial nodes and amygdaloid lymph-glands. He improved greatly under iodide of potassium and mercury, with which, however, it is right to add, cod-liver oil was given; and when last seen he had gained weight, was free from pain, and able to resume work.* (3) A strong and muscular seafaring man about forty, who had symptoms and physical signs resembling phthisis, but was well nourished and had a good appetite. A gumma was discovered near the hip-joint; he was put on iodide of potassium, and under this treatment not only did the node disappear, but his cough and other pulmonary symptoms ceased, and he was to all appearance cured. (4) A patient seen with Dr Miller, of Norwood, who had certainly suffered from syphilis, and in whom there were physical signs of very local consolidation in one lung, together with laryngeal ulceration and hæmoptysis. He was treated with mercury, but died from stenosis of the air-passages before much good could be effected. An autopsy was obtained, and beside deformity and contraction of the trachea and bronchi, there were several gummata in the right lung, with scarring and fibrous induration. (5) A patient in Guy's Hospital, aged forty-two, with signs of chronic disease of the lungs, which had been called consumption, and with no history or signs of past syphilitic lesions. The nature of the case was not recognised until after the man's death from eclampsia. Previous to this severe caries of one ulna had led to such extensive suppuration that the arm was amputated. At the autopsy were found caries of the frontal bone with pachymeningitis, fibroid testes, and two small fibroid patches in the left ventricle. The two primary bronchi were contracted and deformed. The right lung contained a single fibroid nodule in the lower lobe; the left was solid in patches, firm and grey, with dilated tubes. There was nothing that could be called tubercular in either lung, the larynx and ileum were healthy, and there were no miliary tubercles anywhere to be found ('Path. Trans.,' 1877). Microscopical examination of the indurated tissue in the lung showed it to consist of a fibro-nuclear growth with numerous vessels. (6) A sailor aged forty-four, in Guy's Hospital, February, 1876. There were signs of chronic phthisis with hæmoptysis; a history of chancre, but none of secondary lesions, and intense dyspnœa, evidently from obstruction to entrance of air. The larynx was perfectly normal, and there were no signs of aneurysm or thoracic tumour pressing on trachea. Tracheotomy was therefore not performed, and the

* This case closely resembled one recorded by Dr Walshe on p. 513 of his 4th edition.

patient died six days after admission. There was found after death ulceration with stenosis of the trachea, "fibroid phthisis" with one old vomica and much puckering and cicatrisation. There were scars on the surface of liver, but no actual gumma. The liver and kidneys were lardaceous.

Between *syphilis pulmonum* and chronic interstitial pneumonia (so-called fibroid phthisis, or cirrhosis of the lungs) there is no anatomical distinction but the presence of gummata. But we have two unfailing criteria, one in the associated changes in other viscera, the other in reaction to treatment.

Syphilis is no protection from true phthisis, and what has been called syphilitic phthisis is in most cases nothing more than true tubercular phthisis in a syphilitic subject, which runs its course uninfluenced by the latter disease. But there is also a form of chronic pneumonia, with fibroid induration and bronchiectasis, with irregular local distribution, with no tubercle and little or no caseation, which starts either from gummata or from thickened patches of pleura, or from a chronic contracting peribronchitis. This peribronchitis is associated with an ulcerative inflammation of the trachea or bronchi, or both, which is closely related to the ordinary syphilitic inflammation of the larynx. The symptoms during life are indistinguishable from those of ordinary phthisis, though the physical signs point to a more chronic and fibroid, less acute and caseous, form of disease. If the physical signs are confined to one lung and absent from the apices, one may suspect the true nature of the case; but it is only by concomitant lesions of other organs and by the effect of treatment that we can establish the diagnosis during life. Hæmoptysis is often a striking feature. Dr W. H. Porter, of New York, mentions tenderness of the tibiæ and sternum on pressure as a symptom of value. The absence of the bacillus tuberculosis is a most important diagnostic sign during life.*

Hereditary syphilis of the lungs.—It is quite possible that some of the cases of gummata with cicatrices and chronic induration just described may be due not to acquired, but to congenital syphilis.

But there is another form of pulmonary disease which appears to occur only in children who show signs of hereditary lues. It is uniform, without gummata or cicatrices, and with no primary lesion of the trachea and bronchi, or of the pleura. Lungs in this condition have been described by Wagner and Virchow in Germany, by Robin in France,† and by Wilks and Moxon in this country, as a diffused form of hepatisation, firm, dense, or even tough in texture, white in colour, and airless. They are sometimes both affected, more often one, either throughout a lobe or in smaller circumscribed masses. The more universal cases are, as might be supposed, found in stillborn children, or in those who only survive birth a few days. The condition seems to be essentially chronic thickening of the alveolar walls and of the interlobular septa, whereby the alveoli are compressed, and the part affected rendered heavy, bulky, and more or less completely solid. On certain points there is conflicting evidence. Some writers describe the diseased patches or lobes as quite exsanguine with obliterated capillaries; others speak of free production of new vessels, so that the new growth is very vascular. Dr Greenfield described the lung of a presumably syphilitic child, twelve months old, in the 'Pathological Transactions' for 1876 (xxvii,

* Beside the papers quoted above, the following may be mentioned:—Dr Porter ('New York Med. Journ.,' July, 1885), with plate; Dr Moxon ('Guy's Hosp. Rep.,' 3rd series, vol. xiii, p. 374); Dr Goodhart (*ibid.*, vol. xxv, p. 31); the late Dr Wilson Fox's article in 'Reynolds' System;' and Dr Bäumler's in 'Ziemssen's Handbuch.'

† Lorain and Robin call it "epithelioma" of the lungs.

p. 43). It was tough, yellowish white in colour, with a smooth (not granular) section, and exuded very scanty fluid. Histological drawings are given which show bands of fibrous tissue obliterating the alveoli, of which the walls are remarkably thickened, but the endothelium is unaltered. There was unfortunately no positive proof of syphilis in this case; but Dr Goodhart mentions a specimen ('Diseases of Children,' chap. xxii) in which similar *post-mortem* appearances were found in a child three months old, together with undoubted syphilis of the liver. Microscopically, it showed all the features exactly as described by Dr Greenfield —excessive fibro-nucleated growth, extreme vascularity, and collapse of the air-vesicles.

The symptoms observed during life appear to be inconspicuous.

GANGRENE OF THE LUNG.—This affection bears out the statement made with regard to gangrene in general (p. 54), namely, that the death of any part of the human body is always either the result of an intense inflammation, or else of any injury which, if a little less severe, would have set up inflammation, but which by its violence kills the tissues outright before there is time for inflammation to occur.

Anatomy.—Of pulmonary gangrene without antecedent pneumonia it would be difficult to find unequivocal examples. But in the *post-mortem* room cases are sometimes seen in which there has been rapid and extensive sloughing of a portion of a lung, and in which no zone of hepatised tissue separates the gangrenous part from that which is healthy or merely œdematous. In such cases the fact of there having been inflammation is unproven. Generally, however, the sloughing mass lies within a more or less broad area of consolidated lung-substance, of which it had evidently at one time formed a part. Should the disease have proved fatal at an early stage, one condition may gradually merge into the other; should it have reached a more advanced stage, there may be a well-marked line of demarcation, or the dead tissue may have been cast off with the formation of a cavity. Experience in the deadhouse does not support the distinction between two separate forms of pulmonary gangrene, the one "circumscribed," the other "diffuse," though the distinction has been taught since the time of Laennec, who was the first to recognise gangrene of the lungs as a special affection.

The diseased part is of a dirty greenish brown or black colour, and so soft as to be sometimes almost diffluent. It is often horribly fœtid, but occasionally the odour has been little marked, as Cruveilhier long ago noticed. Microscopically, the pulmonary structure is hardly to be recognised, the alveolar walls having broken down into granular detritus.

Origin.—Pneumonia (*i. e.* the acute disease which causes lobar hepatisation) rarely leads to gangrene, except in very old and feeble persons, in drunkards, and in those who are exhausted by some other malady—for example, by diabetes. But one or two instances have occurred in Guy's Hospital, of what had appeared to be an ordinary attack of pneumonia in a healthy subject which, when the acute stage subsided, was followed by symptoms which seemed to indicate that at least some of the hepatised tissues had undergone sloughing. Dr Walshe records just such a case—that of a man who was slowly recovering from an attack of pneumonia of the right lower lobe, when hæmoptysis set in, and was followed by the copious expectoration of a frothy, intensely fœtid sputum, while at the same time physical signs like those which indicate the formation of a cavity

made their appearance. Ultimately this patient left the hospital in fair general health, and free from all physical signs except those commonly denoting consolidation.

Another pulmonary disease, in the course of which gangrene may occur, is phthisis. Dr Walshe speaks of having seen some six cases in which the special fœtor appeared incidentally in connection with *tuberculous vomicæ* already formed. Pulmonary gangrene may also complicate cirrhosis and bronchiectasis.

But in the majority of cases gangrene of the lung arises out of an inflammatory process of *septic* character. There are various ways in which such a process may be set up. Sometimes it is by direct extension from neighbouring parts, as when an ulcerating cancerous growth in the œsophagus eats its way into the lung, or when perforation occurs from a suppurating hydatid or from simple abscess of the liver, or from suppuration spreading from an ulcer of the stomach, or from a putrescent empyema. Sometimes the infection is brought by the blood-vessels. Thus septic emboli may become lodged in branches of the pulmonary artery, either derived from a cerebral sinus, which was inflamed after otorrhœa, or from a systemic vein in the neighbourhood of unhealthy inflammation, or from the right side of the heart in a case of ulcerative endocarditis. In yet other cases the disease starts from the bronchial tubes. A foreign body, as a piece of bone impacted in one of the bronchi, is very apt to set up a sloughing pneumonia; or it may be caused by the entrance into the air-passages of pulpy or liquid food, as in patients who have chronic laryngeal disease, or in those who are comatose from apoplexy, or in lunatics who have to be fed by force. A like result may be produced by matters from the stomach drawn into the lungs during the act of vomiting, especially in persons rendered insensible by anæsthetics; we have had instances of death brought about in this way in cases of hernia or of intestinal obstruction, in which there had been a copious discharge upwards of the contents of the small intestine. Again, putrid materials that pass into the air-passages may be originally derived from the mouth, as in cases of gangrene of the cheek or of the tonsils, of diphtheria of the fauces, or of sloughing cancer of the tongue; Volkmann has suggested that sometimes a severe disease of the ear may lead directly to pulmonary gangrene, from morbid secretions dropping down through the Eustachian tubes into the pharynx, and not (as is more usual) through the occurrence of thrombosis and embolism. Lastly, there are cases in which a sloughing pneumonia is due, not to the entrance into the bronchi of matters from without, but to the decomposition of retained secretion.

Sputum.—In fœtid bronchitis, as we have seen (p. 975), the patient's breath and his expectoration may have either the true odour of gangrene, dependent upon the decomposition of dead tissues, or a peculiar nauseous acrid odour, which is sometimes not unlike that of fæcal matter, and which appears to be due to the presence of free fatty acids.

In the latter case the sputum presents the further peculiarity of separating into three layers, in the lower of which are found certain masses or "plugs," consisting of exudation that has accumulated in the dilated tubes, and undergone chemical and other changes there (p. 974). But the same description does not apply to other forms of sloughing of the lung; for unless there is an antecedent bronchiectasis, the peculiar "plugs" cannot be formed, nor is there any reason why fatty acids should be set free. The odour in all other cases is simply that of gangrene—an indescribable

fœtor, but one which is always of the same character, though it varies greatly in intensity, being sometimes only just perceptible, sometimes so strong as to poison the whole air of a room. As a rule, the patient's breath has the same smell as the expectoration, especially after coughing; and it now and then happens that the breath is characteristically offensive for some days, while the sputum remains odourless. Moreover, there are cases in which during life no fœtor is discoverable, either in the breath or in the expectoration, so that the presence of gangrene may not be suspected until it is seen at the autopsy. Hertz (in 'Ziemssen's Handbuch') accounts for the fact by assuming that the tubes passing from the sloughing parts are obstructed by secretion. But, judging from experience in the deadhouse, it would seem that fœtor is most often absent before death in cases of acute gangrene, which would be commonly described as belonging to the "diffuse" variety of the affection, and in which, therefore, it is most unlikely that obstruction of tubes would be present.

The fœtid sputum of gangrene of the lung is commonly of a dirty grey or greenish colour; sometimes it is brown or almost black, from the presence of altered blood. The microscope does not often lead to the detection of recognisable fragments of pulmonary tissue, although such fragments are so often to be found in cases of phthisis. Obvious hæmoptysis is said to occur seldom in adults, but frequently in children. Fatal hæmorrhage, due to the erosion of a large vessel, is an event of great rarity. When the surface of the lung is affected the pulmonary pleura usually gives way, leading to the formation of pneumothorax, which is quickly followed by septic pleurisy. If there should happen to be local closure of the serous cavity by adhesions, it is said that a subcutaneous emphysema may develop itself, or that an abscess may form, which may open externally after burrowing to a greater or less distance. Another occasional effect of the presence of a patch of gangrene in the lung is said to be the dropping of putrid matters into tubes belonging to other parts of the organ, so as to set up sloughing in them also. In this way, according to Hertz, the diffuse form of gangrene may arise out of the circumscribed.

The only *physical signs* that can be said to belong to gangrene of the lung are such as serve to indicate the formation of a cavity in the organ at a spot where the tissue previously was either healthy or simply consolidated. But it can be only in very rare cases that such signs are to be definitely made out. They would include amphoric breathing, consonating or metallic râles, and loud bronchophony. When there is a possibility of the presence of phthisis, the mere detection of a cavity proves nothing as to the exact seat of the sloughing process, unless it is known that no vomica existed at the same spot before the fœtid expectoration began.

The general *symptoms* that accompany gangrene of the lung are often very severe, but it does not seem that they point to the presence of this affection so definitely as might be supposed from the statements made by most writers on the subject. It is said, for example, that the pulse is small, feeble, and very frequent, and that the pyrexia quickly passes into an adynamic form, with great prostration of the vital powers. That absorption of putrid matters into the blood from the lung should produce such results is, indeed, to be expected; but when the characteristic fœtor is absent it surely is not possible for anyone, from the intensity of the general symptoms alone, to suspect that sloughing of the lung is taking place. In ordinary pneumonia the patient often falls into a similar condition before

death; and the same may be said of many other diseases that sometimes lead to pulmonary gangrene. Nor does it appear that when the sloughing part is very limited in extent the nature of the morbid process is commonly to be inferred from the fact that the constitutional symptoms are disproportionately severe. The truth rather is that in such cases the patient's general condition often remains for several weeks much better than might have been anticipated. Hertz, indeed, speaks of anorexia and gastric disorder, and even diarrhœa, as being caused by the swallowing of some of the offensive material expectorated from the lung, but this would probably be difficult of proof.

Prognosis.—It is only when the gangrene is limited to a small part of the lung that recovery is possible. How minute a slough may cause fœtor is well shown by one of the cases of phthisis complicated with gangrene, which are recorded by Dr Walshe; in that instance the expectoration of a pea-like mass brought the fœtor to an end. Unfortunately he does not say for how long a time it had been present. When a case of gangrene is about to end favourably, the separation of the dead tissue is doubtless followed by the formation of a lining membrane to the cavity left by it, and perhaps this may ultimately shrink and become converted into a fibrous cicatrix.

Treatment.—It is an important point to diminish the fœtor as far as possible, and this applies also to cases of putrid bronchitis (p. 976). The most effectual means of attaining the object aimed at is by inhalations of oil of turpentine, carbolic acid, *oleum cadinum*, or eucalyptol. Turpentine inhalations were used by Skoda about thirty years ago. His plan was to pour a teaspoonful or two of oil of turpentine upon the surface of some boiling water, and to let the patient draw the vapour into the lungs. A better method is to use a Siegel's spray apparatus, so as to atomise a liquid containing from five to two parts of carbolic acid in 100 parts of water, or of a solution of common salt. The inhalations may be repeated two or three times a day. Care must be taken that there is not enough absorbed to set up headache or giddiness, or to give the urine a dark colour. The *oleum cadinum*, or the eucalyptol, may be directly inspired from a sponge placed in an "ori-nasal respirator." The effect of such inhalations is sometimes very striking in cases of fœtid bronchitis.

It is needless to say that the strength of the patient must be maintained by food, and that the administration of stimulants in large doses is sometimes necessary. Ammonia, camphor, ether, quinine, and the tincture of perchloride of iron may each in turn do good service. Oil of turpentine may also be administered by the mouth in doses of twenty or thirty drops, either beaten up with the yolk of an egg, or made into an emulsion with tragacanth or tincture of quillaia.

DISEASES OF THE PLEURA

"Side-stitches that shall pen thy breath up."
The Tempest.

PLEURISY—*Its anatomy—Its physical signs—Pleuritic effusion—Compressed and carnified lung—Dulness—Ægophony—Symptoms—Course and events—Empyema—Diagnosis—of dry pleurisy—of serous effusion—of empyema—Hydrothorax—Hæmothorax—Pleuritic effusion in children—Complications of pleurisy—Its ætiology and relation to tubercle—Prognosis—Treatment of pleurisy and of empyema—Paracentesis and its results.*

PNEUMOTHORAX—*Origin and pathology—Post-mortem characters—Physical signs—Diagnosis and symptoms—Prognosis—Treatment.*

PLEURISY or pleuritis* was mentioned by Hippocrates, and was described by other ancient Greek writers, who undoubtedly were referring to cases of the same disease to which we now apply that name. Nevertheless, it is only during the present century that its real nature has been known to be an inflammation of the two surfaces of the pleura. For, until percussion and auscultation were discovered, there was no possibility of drawing valid distinctions between pleurisy and pneumonia in clinical practice.

Anatomically, pleurisy closely resembles the inflammations of other serous membranes. The earliest morbid appearance is generally said to be injection of the smaller blood-vessels and perhaps the formation of ecchymoses. But, as a matter of fact, one often finds patches of recent lymph upon the surface of a lung without any reddening, when an inflammation of moderate intensity has set in shortly before death, from some other disease; and ecchymoses by themselves indicate, not an early stage of pleurisy, but rather pyæmic infection.

In many instances the effusion of lymph upon the opposed surfaces of the serous membrane occurs only at the very commencement of an attack of pleurisy, of which it forms a "plastic stage." If the morbid process stops here, the case is said to be one of *dry pleurisy*. When the inflammation afterwards subsides, the morbid material sometimes undergoes complete absorption, leaving the pleura in its natural condition, or slightly dull and opaque. But very often the two surfaces have in the meantime adhered together, and remain henceforth connected by separate bands or by a uniform layer formed of connective or fibrous tissue, which may have a free supply of blood-vessels. If the plastic stage, as is more often the case, is succeeded by exudation of serum the case becomes one of pleurisy with effusion.

Signs of dry pleurisy.—There is an auscultatory sign which, when it can be heard, is of itself almost conclusive as to the presence of lymph. This

* Πλευρῖτις sc. *νόσος*, *i. e.* the "side-complaint," the stitch in the ribs. The adjectival termination, *ιτις*, has been taken from this word and from *φρενῖτις* to denote inflammation, and has thus been used to form Peritonitis, Nephritis, Orchitis, and so on.

is the "friction-sound" or "pleuritic rub," due to the movement upon one another of the two roughened serous surfaces. Hippocrates described the pleura as "creaking like leather," and the comparison is often exactly applicable to the sound which is conveyed to the ear from the chest of a patient with pleurisy. Yet Laennec, though he must have often heard this sound, failed to understand its meaning, and left to Reynaud the credit of its right interpretation. Laennec supposed that it indicated emphysema, especially what he described as interlobular emphysema.*

It is difficult to describe in words the characters of this *pleuritic rub*; one must hear it to appreciate them. In its most typical form it consists of an irregular succession of short, harsh sounds, which give one exactly the impression of something catching or dragging against an obstruction and then slipping, but only to catch or drag once more. The patient himself is often conscious of a rough grating sensation each time he breathes; and sometimes one can *feel* the rub by placing one's hand over the affected part of the chest, *i. e.* the vibrations which affect the ear also affect the hand, just as a sonorous rhonchus or a loud cardiac bruit may be appreciated as a tactile vibration or thrill. Sometimes a rub accompanies both inspiration and expiration. Sometimes it is to be detected only at the end of a deep inspiration, when the lungs are just becoming expanded to the greatest possible degree. It may be heard within twelve hours of the commencement of the disease, and in cases of dry pleurisy it may persist for days or even weeks with but little alteration. But it much more often disappears after a short time, because fluid effusion is formed which keeps the two surfaces apart. If the inflammation is spreading, it may, after it has ceased to be audible at one spot, be discovered at another. A rub is not often present over a large area at once. The part of the chest at which one is most likely to hear it is in the axilla, outside the nipple, or in the back outside the angle of the scapula. The reason is not only that pleurisy more frequently affects the surface of the lower lobe than that of the upper, but also that the descent of the diaphragm causes an actual movement of the pulmonary upon the costal pleura, which is wanting elsewhere. Sometimes, however, a rub can be heard over the front of the chest as high as the clavicle.

Another variety of pleuritic rub is equally diagnostic. Instead of resembling the tearing of thick paper, it is, as Hippocrates heard it, just like the creaking of thick leather. The rhythm and its locality are the same. The "grating" rub is more like a râle; the creaking rub more like a rhonchus. Both when heard are very characteristic. But in some cases, a sound which is really due to pleural friction is so ill defined that one cannot distinguish it from moist or dry sounds in the bronchial tubes. This has long been taught at Guy's Hospital. In his well-known paper on the "Difficulties and Fallacies attending Physical Diagnosis," Addison cited a case of Dr Barlow's, in which lymph upon the adjacent surfaces of the liver and of the parietal peritoneum caused a "crepitus, which closely

* There are still some who think that this (or a precisely similar sound) may be due to emphysema (p. 971), or to miliary tuberculosis of the pleura. Again, Dr Walshe has expressed the opinion that a friction-sound may be heard when there is no lymph whatever, if the serous membrane is rough from "simple vascularity." But this conclusion appears to be hardly warranted by the case from which he drew it. Death occurred sixteen days after a rub had been heard, whereupon fluid was found in the pleural space, but no plastic exudation. May not lymph have existed previously, and have undergone disintegration, or absorption by leucocytes?

resembled a mucous rattle" ('Collected Works,' p. 87). It is hardly possible to obtain positive proof of the fact so far as regards the pleura itself, because, even if an autopsy shows lymph upon the serous membrane, one cannot be quite certain that an adjacent tube may not during life have contained fluid secretion.

The locality and the fact that coughing does not alter the sound, as well as the rhythm, usually help us to a correct diagnosis; a rub is very rarely heard near the apex, it is undisturbed by expectoration, and it is most often heard at the end of inspiration, instantly checked by the pain which is felt, never during expiration alone.

The only other physical signs of the plastic stage of pleurisy are a certain degree of impairment of movement of the affected side of the chest and a corresponding enfeeblement of the respiratory murmur.

Pleuritic effusion.—In most cases of pleurisy liquid is effused into the serous cavity, often in large quantity and with great rapidity. Two or three quarts are not uncommonly found, and Watson cites a case in which Crampton, of Dublin, drew off from the left pleura as much as fourteen imperial pints. The liquid is commonly translucent and of a yellowish colour, perhaps containing shreds and floating masses of fibrin. It has an alkaline reaction; according to Fräntzel, who writes on pleurisy in 'Ziemssen's Handbuch,' its specific gravity may vary within wide limits, from 1005 to 1030. In other cases it is more or less opaque, and on standing throws down a layer of greenish-yellow pus. Or it may be altogether purulent; in which case its reaction to test-paper is acid. This constitutes what is termed an *empyema.** As a rule, no doubt, the formation of pus in the pleural cavity is a gradual process, the liquid being at first serous or sero-purulent, and becoming more and more opaque as the leucocytes in it increase in numbers; in such cases both the parietal and the pulmonary surfaces may still remain coated with more or less thick layers of fibrin. But when the inflammation is from the first exceptionally violent—as, for instance, when it is set up by the entrance of putrid matter from without—primary suppuration may occur, and the pleura may remain as smooth and shining as the peritoneum under similar circumstances.

Purulent, as compared with serous pleuritic effusion, is far more common in children than in adults. It is the rule after admission of air to the pleura and in septic or traumatic cases, and also when secondary to variola, but is rare when secondary to rheumatic fever, to Bright's disease, or to cancer, and not common when of tubercular origin.

Sometimes a pleuritic effusion is of a deep brown or purple colour, from admixture of blood. This may be due to the fact that the patient has scurvy or purpura; or it may depend upon the presence of tubercles, or of cancer. According to Fräntzel, "a hæmorrhagic tubercular pleurisy" is less rare in persons advanced in years than in those who are younger; but the only example of it that has been lately met at Guy's Hospital was in a man aged thirty-five. The same writer hints at cases, comparable with hæmorrhagic pachymeningitis, in which after connective tissue has already been

* In England the meaning attached to the word *empyema* is, that of a collection of pus in the pleural cavity. But on the Continent, in spite of etymology, collections of serous fluid, and even of blood, are included under the same name (see Littré and Robin's 'Dictionary'). It has also been used as a synonym for thoracocentesis, so that when the pus escapes through an intercostal space, and has to be let out with the knife, an *empyema necessitatis* is said to arise.

formed as the result of a pleurisy, fresh inflammation is lighted up attended with extravasation of blood; but he does not say that he has actually met with such an instance. The author once removed five ounces of liquid of a dark brown colour from a patient who had pleurisy as a sequela of scarlet fever. He rapidly recovered.

Liquid pleuritic effusion usually gravitates into the most dependent part of the serous cavity, whatever may have been its starting-point. Thus, at the commencement of the disease, lymph may have covered the front and side of the lung, but when serum or sero-purulent fluid is poured out, it falls into the back and lower part of the chest if the patient is in bed, or it accumulates above the diaphragm if he is not recumbent. But this rule is liable to exceptions, when portions of the lung have previously become fixed to the chest-wall as the result of a former attack of pleurisy, or when adhesions rapidly develop early in the illness. Thus a considerable quantity of liquid may accumulate somewhere towards the upper part of the pleural sac, or between the lung and the pericardium, or between two lobes of the lung itself, without there being any in the usual position at the base. And even when the whole of the serous membrane is affected the seat of a serous or purulent effusion may be more or less irregularly circumscribed. Between 1873 and 1876 four instances of this occurred in our *post-mortem* room. In one case there was a broad adhesion to the lateral region of the chest and another to the diaphragm, so that the liquid filled the upper part of the pleural cavity while crepitant lung-tissue still existed in the lower part. In another case there was liquid at the base behind, and also above the root of the lung, with an intervening zone where the lung was firmly adherent. But the limitation of pleuritic effusion by adhesions is seldom so complete as to lead to the formation of two or more collections of fluid entirely cut off from one another; generally speaking, they communicate freely, as can be shown at an autopsy by passing a bent probe behind the bands of adhesion from space to space.

A necessary consequence of the presence of liquid in the pleural sac is that the lung becomes *compressed*, reduced in size, and at last emptied of its blood as well as of its air by effusion; but this is a very inadequate way of stating the case. Every physiologist will admit that the elasticity of the pulmonary tissue must lead to its receding as soon as the pressure in the pleural cavity exceeds that of the atmosphere, until it has become collapsed to at least the same extent as when air is admitted into the serous cavity after death. But, further, Lichtheim has proved by certain experiments, quoted above in the chapter on bronchitis (p. 959), that the elasticity of the lung does not become exhausted until the alveoli are completely emptied of all their gaseous contents. The reason why a lung is not rendered altogether airless when the pleural sac is laid open in the dead body seems to be mainly that the walls of the tubes presently fall together and offer a resistance to the further escape of air, which the elasticity of the pulmonary tissue is unable to overcome. And during life an additional force is in operation to empty the alveoli of air, namely, absorption by the blood-current circulating in their walls. A lung undergoes compression by pleural fluid until, when the cavity is full, it is absolutely free from air; and beyond this point it undoubtedly may become compressed until the blood is also driven out of its substance. It appears advisable to mark this distinction by separate names, and a lung which is bloodless as well as airless may be said to be *carnified*, whereas a lung which is merely airless may be

spoken of as *collapsed*. Both terms have long been in use, but not with the precise shades of meaning here assigned to them. A carnified lung has a very peculiar appearance; it has a slaty-grey tint, and is described as being mouse-coloured. Its cut surface is smooth, very firm, and dry, showing the flattened orifices of air-tubes and vessels closely packed together. Sometimes, if bronchitis has existed as a complication, the tubes contain pus; and if pneumonia or œdema should happen to be present, its characters are necessarily modified. The position occupied by a lung entirely compressed by liquid effusion is, as a rule, determined by its root; it becomes flattened against the mediastinum and backwards towards the spine, and if covered by a mass of false membranes its very presence may be altogether overlooked. Probably the notion of patients living on after having "entirely lost one lung," which is now applied to those who have phthisis, had its origin in autopsies made in cases of pleurisy of long standing. But when the organ has previously been firmly fixed by adhesions it cannot thus be driven inwards, and it may lie in the summit of the pleural space or be irregularly pushed to one side or even downwards. The most common deviation from the rule is doubtless when the upper part of the lung is affected with tubercular disease, and there is consequently a solid mass occupying a corresponding extent of the pleural cavity.

When pleural effusion is insufficient in quantity to empty the whole of the lung of air, and when therefore there is no *compression* of the entire organ, the effect on the pulmonary tissue is remarkable. One would anticipate that the elasticity of the organ would lead to a gradual and uniform shrinking of its substance, so that all parts would contain less air than before, without any part becoming completely airless. But the contrary is the fact. Dr Moxon long ago pointed out, when he was Demonstrator of Pathology at Guy's Hospital, that the presence of even a few ounces of liquid in any part of the pleural cavity causes a total collapse of the pulmonary tissue which ought to occupy that space. The writer has since repeatedly verified his observation; and Cohnheim, at p. 190 of vol. ii of his 'Vorlesungen,' makes a precisely similar statement. One often sees a small triangular area of completely collapsed lung at the posterior inferior corner of the organ, or a thin strip of it running up along its posterior margin. Nay, a mere enlargement of the heart, without there being any pleural effusion, may give rise to complete airlessness of the inner surface of the left lung; and distension of the abdomen, thrusting up the diaphragm, may cause a similar affection of the lower surface either on one side or on both. The explanation of these remarkable facts can hardly be understood except in connection with the mode of origin of collapse of the pulmonary tissue, which has been discussed in the chapter on bronchitis (*supra*, p. 959). It depends upon the general principle, that, whenever a part of the lung fails to be acted upon by the inspiratory forces, it becomes airless, notwithstanding that the tubes which serve it remain patent.

The production of local collapse of the lung-substance as the result of the effusion of moderate quantities of liquid into the pleural cavity has important clinical bearings. It accounts for a circumstance which has long attracted the attention of clinical physicians, namely, that temporary changes of posture on the part of the patient often fail to alter the position of the liquid within the chest, so far as one can tell by percussion. The statement

was once made by a great teacher of medicine, that, whereas in a chronic pleurisy the effusion could be made to gravitate to a different part of the pleural cavity, this could not be done in acute pleurisy, because it was held in the meshes of fibrinous exudation. But surely it is quite the exception to be able to elicit evidence of gravitation, even in chronic cases, although paracentesis is followed by a free flow of liquid through the trocar. Even if one can alter the level of dulness by making the patient sit up, the alteration does not amount to more than a finger's breadth or two. The contrast is very great between these results and the free gravitation in cases of hydro-pneumothorax. If a certain part of the lung is rendered altogether airless by pleuritic effusion, the fluid may (as it were) be *held up* in a fixed position in opposition to the force of gravity.

When the liquid is purulent, even when its quantity is not very large, one can often in thin patients make out that the intercostal spaces are less depressed and offer more resistance to the finger than on the sound side; and when the pleural cavity is full of effusion the ribs may be obviously wider apart, and the spaces between them may bulge or (occasionally) yield fluctuation. This, however, is but seldom observed in the case of serous effusion. On measurement one generally finds, if there is much liquid, that the affected side is enlarged, and sometimes the difference between the two halves of the chest is considerable. In determining this Dr Gee's cyrtometer is very useful. The play of the ribs in respiration is greatly impaired, much more so than during the plastic stage of pleurisy. Moreover, in consequence of the extent to which the sternum is carried forwards, the movement even of the unaffected side during breathing may be much diminished.

Displacement of organs.—Long before the lung has undergone complete compression, other adjacent structures feel the pressure of the effused fluid. The mediastinum is pushed over to the opposite side, the elasticity of the unaffected lung no doubt assisting to displace it. Thus if the pleurisy be on the right side, the apex-beat of the heart is felt and seen during life to be situated further to the left than usual; it may lie some distance outside the left nipple. This dislocation of the heart is, however, much more readily produced if the disease be on the left side. The apex-beat may then be in the epigastrium, between the sternum and the right nipple, or even to the right of the nipple, while in its normal position no trace of pulsation can be detected. Some observers have supposed that in such cases the heart swings over like a pendulum, and that its long axis is now directed downwards and to the right, so that the part which beats against the chest-wall is still the apex of the left ventricle. But nothing seen in the deadhouse supports this opinion. Probably the displacement of the heart is attended with little change in the inclination of its axis, and the impulse is given by some part of the right ventricle.

As above noted, displacement of the heart is much more obvious and extensive when the effusion is in the left pleura than when in the right.

The cardiac sounds have occasionally been found altered under these circumstances. Dr Hope heard a systolic murmur over the aorta, which disappeared when the pleuritic fluid underwent absorption. Dr Walshe met with a case in which each sound of the heart was more or less masked by a blowing murmur for several successive days, while effusion into the left pleural cavity was at its height. He thinks that the diastolic murmur

must certainly have depended upon displacement of the heart, producing tension of the aorta.

It is of some importance to know what amount of liquid is required in order to produce a perceptible cardiac displacement. Fräntzel says that effusion scarcely ever reaches up to the third rib without affecting the position of the apex-beat to a greater or less extent, and that even smaller amounts of liquid often suffice. He also observes that in children the heart is more easily thrown out of its place than in older persons. Another point mentioned by him is that when there have been previous adhesions between the pericardium and the left lung, pleurisy on the left side may cause the heart to be carried backwards away from the chest-wall, so that no impulse whatever can be felt or seen. But when the amount of effusion is moderate, the normal apex-beat may be absent without there being any discoverable impulse elsewhere, the reason probably being that the sternum conceals it. In all cases of this kind the stethoscope must be used with the object of determining the spot at which the cardiac sounds are heard loudest.

The diaphragm is pushed downwards whenever the amount of pleuritic effusion is at all considerable. The displacement of the liver or of the spleen may be recognised by percussion, or one or the other may be felt projecting below the ribs.*

Physical signs of effusion.—In the clinical recognition of pleuritic effusion we depend on physical examination of the patient. Several signs already mentioned must be carefully sought for; these are enlargement of the affected side, impairment of its movements, an altered state of the intercostal spaces, and displacement of the thoracic and abdominal organs. There remain the results of percussion and of auscultation; and of these two methods the former is by far the more valuable, as was long ago maintained by Piorry, in opposition to Laennec.

Dulness on *percussion* is, in fact, the main sign of pleuritic effusion. The percussion-sound becomes altered long before there is any evidence of pressure upon adjacent viscera. A circumscribed collection of serum and pus may of course cause dulness of any part of the chest, but when fluid lies free in the pleural space, the dulness is to be made out first at the base behind. One must not, however, suppose that small quantities of fluid ought always to be discovered by this means. Wintrich long ago declared that eight or ten ounces could scarcely be detected with certainty, and a considerably larger amount may sometimes escape recognition.

Much depends upon the habitual posture of the patient. If he is sitting upright in bed, the diaphragmatic, rather than the posterior, surface of the lung becomes compressed, and the percussion-sound may at first be scarcely altered. If he is lying down, the fluid is more or less spread out over the back. When the percussion-sound down to the very bottom of the lung is perfectly resonant, one may feel sure that effusion, if present at all, is in such small quantity as to be clinically unimportant.

The dulness caused by fluid in the pleura differs from that produced by consolidation of the lung in being more absolute, and in the greater sense of resistance which it conveys to the finger in percussion.

* According to Fräntzel, when the distension of the pleura is extreme, it is sometimes possible to detect an elongated, tense, fluctuating swelling, which protrudes below the costal cartilages, and which is nothing else than the front part of the diaphragm.

If the effusion is large, the whole of the back and side of the chest are devoid of resonance. It is remarkable in such cases that over the front of the chest—below the clavicle, and downwards nearly to the nipple—the percussion-note is subtympanitic. Skoda first pointed out this fact, which remains associated with his name. Its explanation is still doubtful. German writers are content to ascribe it to "relaxation of the pulmonary tissue;" Dr Walshe thinks that it depends upon the presence of air in the minute tubes of the carnified lung, so that a condition essential to its production is that these tubes should not have undergone compression as well as the lung-substance. The explanation suggested by Dr Bristowe is the diminution of the vibrating area formed by the thoracic walls (p. 929).

Auscultation is of less assistance than percussion in the detection of pleuritic effusion. In many cases one finds that the breath-sounds on the affected side of the chest are enfeebled, indistinct, or altogether wanting. But, not infrequently, tubular breathing is audible over part of the compressed lung, and in some exceptional cases this can be heard so extensively that one might suppose the air to be entering freely everywhere.

The same curious uncertainty applies to *auscultation of the voice*. As a rule, it is conveyed to the ear more feebly than on the healthy side of the chest; but sometimes there is bronchophony, and this may occasionally be extremely loud. There is, however, one modification of vocal resonance which, when present, is very characteristic of pleural effusion. It was discovered by Laennec, who called it *ægophony*, from its resemblance to the bleating of a goat. He also compared it to the artificial voice of "Punch" in the street (p. 940, *note*). Both these comparisons are excellent, and the sign is readily caught even by an untrained ear. It may be described as high-pitched, tremulous bronchophony, with a nasal twang. With regard to the frequency of this sign, widely opposed statements have been made by writers in consequence of their differing as to the definition of the term. Almost all the best observers are agreed that what may be called *pure* ægophony is rare, and seldom lasts more than a few days. But between it and bronchophony there are all degrees of transition; and if one is to speak of the voice as ægophonic in every case in which it reaches the surface of the chest with more or less of a twang, there are very few instances of pleuritic effusion in which this change in its character is altogether absent. In one particular region ægophony is observed far more frequently than elsewhere, namely, about the inferior angle of the scapula, and round towards the axilla. But sometimes it is heard in front, near the nipple, or even close to the clavicle.

Its production is believed to depend upon the presence of a rather thin layer of liquid between the lung and the parietes (cf. p. 940). Consequently it generally disappears as the effusion increases, unless there are adhesions, which keep the lung fixed at a certain distance from the surface of the chest. But in some rare cases, not explained by the existence of adhesions, ægophony may persist in spite of abundant accumulation of fluid; and, according to some experienced auscultators, it is sometimes present when there is no fluid effusion at all. Dr Walshe points out that one source of fallacy lies in the possibility of overlooking the fact that the ordinary voice of the patient is shrill and tremulous, as it so often is in women of advanced age. Again, bronchophony may acquire a nasal twang if the nostrils are closed, just as the ordinary voice does.

With pleural effusion the *tactile fremitus* felt when the patient speaks is

diminished or absent, a sign which is often of value in distinguishing this condition from solidification of the lung. Nevertheless, in exceptional cases vocal fremitus is palpable.

General symptoms.—The symptoms of pleurisy vary widely in severity. They are sometimes so marked as to suggest the nature of the case at once; they are sometimes almost, if not quite, absent.

Foremost among them is *pain* in the side, the *point de côté* of French writers. This is often very violent, and of a sharp tearing or cutting or stabbing character. It is increased both by movement and by pressure, but more by a deep breath, by a laugh, a cough, or a hiccup. The patient, therefore, breathes in a shallow, jerky manner. His cough, if he coughs at all, is short and half suppressed, and he abstains as much as possible from laughing or sneezing. He lies during the early part of his illness on his back and on the unaffected side, and he shrinks from percussion. The severe pain contrasts strikingly with its absence in bronchitis and pneumonia. It is comparable to that of the inflamed peritoneum, and, like it, is excited or greatly increased by pressure. Hence the pain on breathing and the relief obtained by restraining the movements of the chest by bandages. Cruveilhier rightly accounted for the fact that its seat is so often limited to the lower part of the chest—about the nipple or between the fifth and eighth ribs—since here there is so much more movement of the visceral upon the costal pleura than higher up. But the pain is sometimes felt in the shoulder, in the armpit, or beneath the clavicle. In exceptional cases it is referred to the terminal branches of the intercostal nerves; to the hypochondrium, so as to lead to a mistaken diagnosis of hepatitis; to the loins, so that the case has been called one of lumbago; or to the neighbourhood of the umbilicus, so that peritonitis has been suspected.*

In some cases pain is altogether absent, and thus a large quantity of effusion may accumulate in the pleural cavity without its presence being thought of. Fräntzel says that this is apt to occur in children, in very old people, and in lunatics. It often happens that pain subsides or disappears towards the end of the first week, or even after two or three days.†

Next to pain, *dyspnœa* is the most striking symptom of pleurisy. The breathing is short and jerking, but it is also increased in frequency, especially when the patient exerts himself, as in lifting anything or in going upstairs. Sometimes the scaleni and the other muscles of forced inspiration are brought into action; and the nostrils dilate each time air is drawn into the chest. As effusion accumulates, the patient begins to find that he can lie over towards the affected side more comfortably than in any other position, because the weight of the fluid is then removed from the mediastinum. He often has orthopnœa, for the diaphragm works more freely while the upright posture is maintained. Sometimes there is lividity of the cheeks and lips.

The dyspnœa of pleurisy is generally more marked in robust plethoric patients than in those who are anæmic and wasted. As Andral long ago pointed out, it sometimes happens that pleurisy scarcely interferes with the

* I have myself had a patient whose sole complaint was of pain in the crista ilii; I feel sure that if it had not happened that a short while before my attention had been specially directed to this question, I should have failed to discover that he had pleurisy, although on applying my stethoscope I at once heard a rub.—C. H. F.

† Laennec, and afterwards Gerhardt, declared that the pain of pleurisy was sometimes seated upon the opposite side of the chest to that which was inflamed, but this would require more evidence than that of authority for us to accept it.

patient's comfort. He had a patient who went on with his work as a carter, in spite of an enormous effusion into his pleura; and Watson speaks of a butcher, who in the same condition was convinced that he was well, and fit to leave the hospital.

Cough is seldom entirely absent in pleurisy; and there appears to be no doubt that it may occur independently of any affection of the lung or of the bronchial tubes. Sometimes it can be excited by percussion or pressure over the painful intercostal spaces, or by changes of posture. During the operation of *paracentesis thoracis* it may be produced by movements of the trocar. In his experiments on animals Kohts found that it was caused by irritation of the parietal, but not of the pulmonary, pleura. The cough of uncomplicated pleurisy is dry, *i. e.* unattended with expectoration.

The *pyrexia* of pleurisy is generally moderate. The disease, when uncomplicated, seldom sets in with a violent rigor. But slight chills returning day after day are observed in many cases, especially when the patient remains out of bed during the day. The temperature commonly ranges at about 101° or 102°, but in the most severe forms of the disease it may reach 104°, or even higher in children. In persons suffering from cancer, or from chronic renal disease, there may be no pyrexia at all. The pulse is accelerated. Fräntzel insists upon the importance of watching it with care; for as effusion goes on, although the temperature may fall, the pulse not only becomes more rapid, but its volume and tension diminish, in consequence of the obstruction to the flow of blood through the pulmonary vessels. This affords a valuable indication of the degree of danger to the patient's life; and during paracentesis the physician may be able to feel the pulse becoming fuller, and at the same time slower, under his finger, showing the immediate relief given by the removal of the fluid.

Side affected.—It has been thought that pleuritic effusion is much more common on the left side than on the right.* Dr Eddison, of Leeds, in 40 purulent cases found 20 right to 20 left; Dr Richards, of Birmingham, 3 right to 7 left; Dr Griffith, of Leeds, 19 right to 26 left; Mr Godlee, 22 right to 28 left. Of 44 cases of empyema under the writer's care, 16 were right and 28 left. Adding these numbers together, we find that of 189 cases of empyema, 80 were right and 109 left. Cases of double empyema have been recorded in children. Double serous or plastic pleurisy is not uncommon.

Course and event.—The course of pleurisy varies widely in different cases. In the most severe form, which is very rare, but of which Fräntzel says that he has seen three examples, the patient quickly falls into a typhoid state, with delirium, stupor, and a dry fissured tongue: the dyspnœa and lividity increase, so as to threaten his life by the end of the first week; and though paracentesis be performed and repeated, the effusion collects again so rapidly that the fatal issue is scarcely retarded.

Even when the disease seems to be attended with no alarming symptoms one must never regard it as free from danger, if the amount of effusion is large. Death sometimes occurs quite suddenly and unexpectedly. In 1874 this happened to a patient in Guy's Hospital with double pleurisy, who a short time before had been seen quietly asleep. For some days previously this patient had had much dyspnœa, and it seems not unlikely that the im-

* "That pleurisies are *only* on the left side is a popular tenet not less absurd than dangerous" (Sir Thos. Browne, 'Pseudodoxia epidemica,' bk. iii, chap. 3).

mediate cause of death was exhaustion of the respiratory centre. But in another case, which ended fatally after an hour's extreme distress of breathing on the evening after admission, it was observed that the pulse ceased before the respiration. Here the effusion was on the right side; but there was œdema of the left lung, which no doubt helped to kill the patient.

For the occurrence of fatal syncope, when the left pleura is the one affected, a special explanation has been suggested by Bartels, of Kiel, in the 'Deutsches Archiv' for 1868. It depends upon the anatomical fact (which has been verified after death on several occasions by him and by Frantzel) that when the heart is pushed far over to the right the mouth of the inferior vena cava becomes bent almost at a right angle, just above the quadrilateral aperture in the diaphragm, the wall of the auricle forming a fold which covers a large part of the aperture. This is supposed to interfere with the flow of blood to the heart, especially if the diaphragm is suddenly curved upwards in a fit of coughing, or if a sudden muscular effort is made.*

But pleurisy is not often attended with such risks. The inflammation need not go beyond the exudation of lymph, and after a time it may subside, leaving adhesions which fix the lung to the chest-wall for the rest of life. Whether dry pleurisy necessarily ends thus in adhesion of the affected part, or whether it may not sometimes pass off without permanent traces, is a difficult question. What is well known to every pathologist is the fact that an adherent pleura is often found when there has been no history of any affection of the chest. Dr Gee gives a tracing, made with the cyrtometer, which shows that in a child the chest may be markedly contracted on one side, as the result of a universal closure of the pleural space, without there having been any symptoms to suggest the presence of such a morbid condition. There is no clear evidence that the adhesions left by a dry pleurisy at all affect the health.

The *duration* of an attack of dry pleurisy is sometimes exceedingly brief, often not more than two or three days.†

When pleurisy gives rise to effusion and the amount of liquid remains small, one can express a confident opinion that absorption will take place in time, and that the compressed pulmonary tissue will expand and resume its functions. And even if the quantity should be very large, there is always a possibility that the patient's ultimate recovery may be complete.

Percussion usually affords the earliest indication of the subsidence of pleural effusion. The dulness becomes less extensive and less absolute, not only in front, but also over the upper part of the lung behind. A little later, the displaced organs return to their proper situations, and the side may fall back to its previous dimensions. A feeble vesicular murmur may then be heard where none had been discoverable before. But with regard to this, there is a source of fallacy which must be borne in mind. At a certain stage of pleurisy, even while the affected lung still remains completely flattened and airless (as subsequently appears from an autopsy), the inspiratory sound from the opposite lung is very apt to be carried across

* Trousseau had previously attributed the occurrence of sudden death in cases of pleuritic effusion to "twisting of the aorta and large vessels," as a result of displacement of the heart; but he does not seem to have had the inferior vena cava in view.

† I was once asked to visit a student who had been seized the same day with violent pain in the side, and who told me that he knew he had pleurisy, because he had had the disease before. I heard a very well-marked rub on auscultation, and told him that I should come to see him on the following day. But when I came he assured me that he was well again; and on listening I could detect nothing abnormal.—C. H. F.

the spine in such a way as to suggest that air enters both sides of the chest. It seems that the pleura when overfilled may transmit sounds almost as well as a solid lung (cf. p. 1025, of bronchophony).

Another physical sign which commonly attends the absorption period of pleural effusion is what is termed a "redux rub." This exactly resembles the friction-sound of the earliest stage of the disease, differing (if at all) only in being still louder and in being heard over a more extensive area. It often remains audible for several days or even weeks together, and may be accompanied by a return of pain in the side, without fresh inflammation.

Even when the attack has so far subsided that the patient feels well, and perhaps resumes his occupation, it often happens that the side still remains more or less dull on percussion, and that the breath-sounds over the affected part are much feebler than natural.

Empyema.—If the pleuritic effusion is purulent, it very rarely undergoes absorption, but perforates the pleura, and thus makes its way out of the body. This never happens with a serous effusion.

Sometimes the empyema escapes *through the bronchial tubes.* If this should occur while the patient is asleep, or if he should be so exceedingly feeble as not to be able to expectorate, he may be instantly suffocated. But surprisingly large quantities of pus are sometimes ejected, with much less distress than might have been anticipated. If the opening leads directly into a large tube, air passes into the pleural cavity to take the place of the liquid, and a "pyo-pneumothorax" is established, which will be discussed further on (p. 1043). But in many cases of empyema discharging through the lung no pneumothorax follows. This appeared so remarkable to some of the older physicians, that they supposed that pus was capable of undergoing absorption from the pleura, and of being afterwards excreted from the bronchial mucous membrane. The true explanation was given by Traube in 1872 ('Ges. Abhandlungen,' vol. iii, p. 44). If the pleura alone is eaten through, the alveolar texture of the compressed lung may allow pus to be forced through it by violent coughing, while it yet fails to afford a passage to air in the opposite direction, especially as there is little or no movement of that side of the chest during inspiration.

Such cases often end in recovery, as Hippocrates knew, when he wrote: "Those in whom a pleurisy ends in suppuration, may be cured if they bring up the matter within forty days from the rupture into the pleura" ('Aph.,' v, 15).

In other cases, but far less often, an empyema makes its way outwards *through the parietal pleura.* An intercostal space is then usually perforated; and a soft elastic swelling, of greater or less size, forms beneath the skin, which ultimately becomes reddened, ulcerates through, and allows an enormous quantity of pus to escape. At the present day one seldom has an opportunity of observing this result of pleurisy, because scarcely any practitioner now fails to diagnose a large pleuritic effusion, and to treat it surgically. The point at which perforation is most apt to occur has (in the 'Lancet' for 1882) been defined by Mr Marshall to be in the fifth space, below the nipple; here there is a weak spot in the chest-wall, covered only by the internal intercostal muscle and a thin layer belonging to the great pectoral and the external oblique muscles. But the orifice may be elsewhere, and is sometimes as high as the second space. Or, again, the diaphragm may be perforated by an empyema. In 1865 a man died in Guy's Hospital of an empyema, which had been tapped eleven days previously. A hole,

which had a diameter of a quarter of an inch, was found in the fleshy substance of the diaphragm, and below it was a large circumscribed abscess, which had not opened yet into the peritoneum.

Again, the pus may make its way backwards and point *in the loin*. In 1858 a boy nine years old was in the hospital for pleurisy, and was discharged convalescent. Afterwards he came back with a pulsating swelling in the left lumbar region, which proved to be an abscess and was opened. Two months later the boy died of tubercular meningitis, and an autopsy showed that the left lung was still contracted, and that a sinuous channel, six inches long, extended down from the pleural space behind the diaphragm to the external opening. In one recorded case the pus from an empyema burrowed until it actually reached the popliteal space.

Except when the pus escapes through the pulmonary tissue, the spontaneous discharge of an empyema is almost always followed by a protracted illness, and often ends in the death of the patient. Entrance of air into the serous space renders the contained fluids putrid; and this leads to irritative fever, and to more or less rapid emaciation and exhaustion. If not, the pleural fistula may go on discharging for five, ten, fifteen years, or even longer, until lardaceous changes develop themselves in the abdominal viscera, and cause death by renal dropsy. In one patient under the writer's care, empyema had lasted fourteen years, and when she died at about seventy-two there was no albuminuria nor sign of enlargement of the liver or spleen.

The only chance of recovery in cases of this kind seems to be that the whole cavity should be gradually obliterated by the abundant formation of granulation tissue, and by the contraction of the dense fibrous material which becomes developed from it. This indurated substance sometimes reaches the thickness of an inch. At the same time all the structures which surround the pleura become dragged inwards, so as to reduce it within the smallest possible limits. The ribs fall in and may almost come into contact with one another; they remain motionless during inspiration, or (as was once observed by Dr Gee) their anterior parts may actually recede and move backwards each time that the healthy half of the chest expands and draws the sternum forwards. The dorsal spine becomes curved, so as to present a concavity towards the affected side. The shoulder sinks, the diaphragm is dragged upwards with the abdominal viscera; the mediastinal structures are pulled over, and the heart is often brought so widely into contact with the ribs that its impulse can be seen and felt over a far more extensive area than under normal circumstances.

Diagnosis.—As a rule, the recognition of pleurisy and pleural effusion is easy, being based directly upon the characteristic physical signs. But many practitioners are too ready to set down to this disease cases in which there is no symptom except a *pain in the side*. Hospital practice teaches us to distrust the statements of patients when they tell us that they have been under treatment for pleurisy. It may have been neuralgia or intercostal rheumatism, *i. e.* myalgia; sometimes an eruption of *shingles* has escaped notice, from not having been looked for. Costal *periostitis* and abscess of the chest-wall are other affections the possible presence of which must not be forgotten. The only case in which it is allowable to diagnose pleurisy without positive evidence from percussion or auscultation is when violent pain in the lower part of the chest is increased by each breath and accom-

panied by pyrexia. We may then reasonably suppose that there is inflammation of the diaphragmatic and corresponding pulmonary pleura.

Even when we think we hear a *pleuritic rub*, there is need of caution. Dr Gairdner has recorded an instance in which a sound which he describes as having a shuffling character, attended with a tactile sensation as of a jerking movement, produced by something rubbing up and down against the walls of the chest, proved to be due to emphysema of the lung. And Guttmann cites a case of Jurgensen's, in which a similar effect was produced by tubercles of the pulmonary pleura. It is said that the crepitus of a broken rib has been mistaken for a pleuritic rub.

Frequently what has been called a soft pleuritic rub turns out to be a mucous râle. Another mistake to beware of is that of attributing to pericarditis a friction-sound which is really pleuritic.

Pleuritic effusion has sometimes been diagnosed when the disease (if on the right side) has been a *hydatid* in the liver, or a hepatic *abscess*, or hypophrenic abscess, or when (if on the left side) it has been an abscess between the liver and the diaphragm connected with the spleen. Again, it is remarkable that all the examples of very large chronic *pericardial effusion* which have occurred at Guy's Hospital have been set down to pleurisy. This occurred to the writer in 1889, there being moderate effusion in the left pleura combined with the presence of forty-two ounces of serum in the pericardium in a case of Bright's disease. The accumulation was very gradual and the symptoms remarkably slight. One ought to be on one's guard, and by carefully mapping out the area of percussion-dulness and marking exactly how far it extends in front, at the side, and behind, the figure produced would probably decide the point. No doubt the disease might still be a circumscribed empyema; but at least one would be saved from imagining that the fluid lay free in the pleural cavity, and by paracentesis no harm would probably be done.

When there is a very large effusion of pus into the left side of the chest, pulsation synchronous with the heart can sometimes be felt in the intercostal spaces near the nipple or above it and towards the clavicle, so that the presence of an *aneurysm* may be suspected. A case of this kind was recorded two centuries and a half ago by Baillon; its real nature was cleared up by the bursting of the swelling with discharge of pus. In our own time Dr Walshe and Dr Macdonnell, of Montreal ('Dublin Journ. Med. Sci.,' 1844), have studied "pulsating empyema;" Comby in France ('Arch. Gén.,' 1883), Kepler in Germany ('Arch. f. kl. Med.,' 1887), and Osler in America ('Trans. Assoc. Amer. Physicians,' 1888, p. 330) have collected about forty cases. Its pathology is not clear, but seems to depend on extreme tension, with weakening of the intercostal muscles. Pulsating empyema occurs almost always on the left side.

Again, the physical signs may point to the presence of a large pleuritic effusion occupying the lower and back part of the chest on one side, and yet they may turn out to be due to solid lung. Traube has related a case in which he imagined that there was, besides hepatisation of the left lung, a large pleuritic effusion, but the autopsy showed that the serous cavity had been closed by former adhesions; the great diminution of tactile vibration in this instance was attributed to plugging of the smaller bronchial tubes by lymph. Most English observers follow Laennec in believing that the detection of ægophony is conclusive evidence that there is at least some fluid effusion into the pleura; but Fräntzel declares, as the result of careful

observation directed to this question for some years, that this rule is not invariable, as had, indeed, long ago been asserted by Skoda.

In chronic cases a more serious error may be committed; that of mistaking for pleuritic effusion a mass of *malignant growth*. Every physician of experience must either have seen this mistake made by others or have made it himself. One should therefore never give an opinion without having thought of such a possibility; the points to be especially noticed are whether the area of dulness corresponds in shape with that caused by a distended pleura, and whether tactile vibration is or is not still to be felt in certain positions. It must be borne in mind that a new growth situated in the mediastinum or in the lung is often accompanied by effusion into the pleura, so that a strictly differential diagnosis may after all be less accurate than a more doubtful opinion.

Fräntzel relates a converse case, in which a large hæmorrhagic effusion was for a time supposed to be a solid tumour.

Even when the presence of liquid in the pleural cavity is positively and correctly diagnosed, it is not always due to pleurisy.

Passive dropsy of the serous cavity, or *hydrothorax*, may give rise to precisely similar physical signs, except that, being probably never altogether unilateral, it is not likely to displace the heart. This condition is most common in cardiac disease or in extreme anæmia, but often complicates inflammatory effusion in cases of Bright's disease.

Again, pure blood may fill the pleura, constituting *hæmatothorax*. Apart from surgical injuries, the chief cause of such an affection is the rupture of an aneurysm of the aorta. Watson mentions a case in which caries of a rib led to ulceration of the intercostal artery and to distension of that side of the chest with blood, a large part of which was clotted in concentric layers. The admixture of a certain amount of blood with serum in a pleural effusion is almost certain evidence that the primary disease is either tubercular or malignant.

Diagnosis of empyema is often difficult. One of the chief indications of the formation of pus is the continuance of high evening temperatures after the first two or three weeks; the pyrexia in many instances assumes a regularly hectic type. Œdema of the subcutaneous tissue of the affected side of the chest has long been mentioned as a sign of empyema, but it is often absent where suppuration is going on; and Fräntzel cites a case observed by Traube, in which it was present, but in which a fibrino-serous liquid was withdrawn by paracentesis. The best way of detecting the œdema is to pinch up a fold of skin, and to compare its thickness with that of a similar fold on the opposite half of the body. Fräntzel and Peter each found in certain cases of pleurisy that the temperature of the skin was persistently higher by about a degree Fahr. on the diseased than upon the healthy side of the chest, and in almost every instance the effusion proved to be purulent. As practical rules, we may bear in mind that empyema is far more common in a child than in an adult, that rheumatic pleurisy never is purulent and renal pleurisy rarely, but that tubercular is often so, while traumatic commonly, and pyæmic pleurisy always, causes an empyema. Among adults, empyema is more common in men than in women.

In children, the difficulties of diagnosis of pleural effusion are greater than in adults, especially between it and broncho-pneumonia with extensive collapse; and the temperature affords little help in distinguishing a purulent from a serous effusion, for it is so readily raised in a child. Dr Thomas

Barlow and Mr Parker (in a paper read at the British Medical Association in Manchester, 1877) quote a case of serous pleurisy with a temperature of 103·4°, and of empyema with the highest evening temperature 101·5°. They look upon anæmia and clubbing of the fingers as the best signs of the purulent character of an effusion, but depend on the practical decision of the hypodermic syringe, which has now replaced the grooved needle.

The frequency of empyema in children is illustrated by the following figures quoted in the above paper: out of 44 consecutive cases of pleurisy in the Great Ormond Street Hospital, 27 were purulent, and in another series of 16 cases 14 were purulent.

Complications.—These are rare; pleurisy does not lead to pneumonia, nor directly to phthisis, though it is often secondary to each. It often accompanies bronchitis as the result of a chill, with or without evidence of broncho-pneumonia.

Empyema is generally attended with more or less exudation into the subserous connective tissue. In a case which occurred at Guy's Hospital, in 1872, the surface of the lung was covered with reticulated lines, due to the presence of pus in the lymph-channels beneath the visceral layer of the pleura. In another case, in 1869, pus was found outside the parietal layer of the pleura, infiltrating the intercostal muscles; there was also an abscess as large as a walnut in the mediastinum. In a third case, in 1873, the mediastinal tissues were three quarters of an inch thick from infiltration with puriform lymph. All three were examples of double pleurisy with pericarditis.

The secondary pleurisy of phthisis seems never to extend to the pericardium. But the more intense and violent forms of the disease are exceedingly apt to do so. Moreover, there are cases in which both pleuræ, the pericardium, and the peritoneum become simultaneously inflamed; at least it cannot be determined that one of them was affected first (cf. p. 60). As a rule such cases present very acute symptoms and run a rapid course, but this is not invariable.*

Whenever the two pleuræ are attacked with inflammation simultaneously or in succession, one ought to look for some underlying condition, such as Bright's disease or tuberculosis.

Ætiology.—(*a*) *Of "idiopathic" pleurisy.*—Foremost among the causes of pleurisy is *cold.* This has been so commonly set down as giving rise to all forms of internal inflammation, and often with so little reason, that one cannot be surprised that many physicians are reluctant to recognise its ope-

* In 1876 a woman, aged twenty-three, was admitted into Guy's Hospital with what was supposed to be enteric fever. After a fortnight fluid effusion was detected in the left pleura, and forty-two ounces were drawn off by the aspirator. Her febrile symptoms continued; she became emaciated and died. Towards the last it was naturally thought that she was suffering from tubercular disease. However, on making the autopsy, we could discover no tubercles nor any primary visceral lesion. Beside some pleuritic effusion on the left side there was lymph over the whole of the right pleura; the pericardium was adherent by a recent plastic exudation; the liver and the spleen were fixed to the diaphragm; and the lower part of the abdominal cavity contained some purulent fluid. It may be that the disease was of rheumatic origin, for the patient had a painful affection of her joints about two months before; but there was no evidence of endocarditis, present or past. The case is of interest, not only pathologically, but also on account of its obscurity during life. For the thoracic serous cavities and the upper part of the peritoneal space have been repeatedly found all closed by old adhesions, when there has been no history of any chest affection; and it would now seem that such a result may arise from an illness which clinically might be taken for fever.—C. H. F.

ration (see a lecture by Dr Ransom, of Nottingham). But the clinical evidence of the direct dependence of pleurisy upon cold cannot be explained away. Fräntzel cites, for example, cases of persons who have been attacked after having exposed one side of the body to a draught in changing their clothes while heated, or after having got one side wet through in a driving rain. Other cases have immediately resulted from sitting near an open window or a badly fitting door, especially during convalescence from some acute illness.

Injuries to the chest may give rise to pleurisy. Not only does this occur when the ribs have been broken, but sometimes when there is no evidence of damage to the walls of the chest.

(*b*) *Of secondary pleurisy.*—Certain general diseases are very apt to be attended by pleurisy as a complication. This is the case with acute *rheumatism;* but rheumatic inflammation of the pleura occurs only during the fever, not independently of it, as with pericarditis or endocarditis. It is very difficult to prove the rheumatic origin of the serous inflammation in any other cases, and it is much better not to assume it.* Scarlet fever must also be mentioned. Fräntzel lays down the rule that enteric fever never becomes complicated with pleurisy during its early stage, while the morning temperature is below 102°; and it is not frequent later.

Among chronic affections none is so commonly accompanied by pleurisy as *Bright's disease;* so that the urine should always be carefully and repeatedly tested for albumen.

Secondary pleurisy is often due to the direct extension of inflammation from some adjacent structure. To the pathologist there is probably no condition which is so familiar as this; but the affection is in many cases found to be quite recent and early at the time of death, so that it has no clinical significance. Among the less obvious starting-points for a severe or even fatal pleurisy may be mentioned abscesses in the armpit, operations upon the breast, suppuration of the cervical connective tissue after tracheotomy, caries of the ribs, mediastinal abscess, cancer of the œsophagus, and caries of the dorsal vertebræ. Or its origin may be below the diaphragm, the connecting lymph-channels discovered by Recklinghausen probably conveying the inflammatory process from one serous cavity to another. Thus pleurisy which was the immediate cause of death has been found to be due to extension from a peritonitis of puerperal origin, or following ovariotomy, or arising from disease of the rectum. Again, a very acute inflammation of the pleura, with fœtor of the pus, has started from the upper end of a psoas abscess, or from a localised abscess behind the stomach due to a perforating gastric ulcer. Mediastinal growths without inflammation frequently produce pleuritic effusion; so also do malignant tumours of the walls of the chest or of the mamma.

Dry pleurisy occurs in every case of acute *pneumonia*, and we must remember that what seems to be an uncomplicated and simple attack of pleurisy may really be dependent upon extensive pneumonia, of which there is sometimes little or no clinical evidence. When pleural effusion has once taken place it may be impossible to discover by physical signs the presence of hepatisation of the corresponding part of the lung. It often happens that the characters of the sputa afford the only clue to the real nature of the case, or a correct diagnosis may depend entirely upon one's having seen the patient at an earlier period, before the fluid was poured out into the serous cavity. Again, it is not improbable that a very limited patch of pneumonia,

* By "rheumatic pleurisy" many writers only mean pleurisy due to catching cold—a misleading use of the term.

involving the surface of the lung, may sometimes be the starting-point of a diffused and severe pleurisy.

In *pyæmia* (especially when resulting from thrombosis of the cerebral sinuses, itself consequent upon disease of the temporal bone) pleurisy is sometimes the most conspicuous feature of the case, and may be mistaken for the primary disease, and the cause of all the patient's symptoms.

The relation of pleurisy to *phthisis* is of the greatest importance, on account of its bearing on prognosis. One is frequently seeing patients who, having favourably passed through an attack of pleurisy, are shortly afterwards seized with hæmoptysis, or develop signs of tubercular disease of the lungs. Sometimes, no doubt, the presence of such disease can be detected, even while the serous inflammation is in progress, if one is careful to examine the upper lobes thoroughly. But in many cases all the clinical evidence points to the conclusion that the pulmonary affection has been of later development. Those who adopt Buhl's infective theory of tubercle might maintain that it is really secondary, and due to the absorption of caseous matter into the blood. But the primary pleuritic inflammation is almost always of a serous, not a purulent character, and it is far more probable that it is due to a few pulmonary tubercles on the surface of the lung setting up irritation and effusion.*

It is a curious question whether pleuritic effusion, while it continues to compress one of the lungs, favours a fresh development or a further growth of tubercles in that organ, or whether it may not rather be adverse to such an occurrence, even though it may increase the susceptibility of the other lung, which has to perform extra work. The following six cases bear on this question. In one there were no tubercles except in the opposite lung; in another the tubercles were much less numerous on the side of the pleurisy; in two others it was observed that on that side they were all of old date and inactive. On the other hand, there was one case in which they were more abundant in the compressed lung than in the opposite one; and once a lung entirely airless was full of tubercles (some grey and others caseous) in its lower lobe, where their presence, the apex being healthy, is an occurrence so exceptional that one could hardly doubt that the pleurisy had determined their formation.

On the whole, it is important to remember that, excluding traumatic cases and direct exposure to cold, the majority of cases of pleuritic effusion in young adults, if not occurring in the course of Rheumatic Fever, are tubercular, and that the majority of cases in elderly persons are renal or secondary to malignant disease.

Prognosis.—This depends chiefly upon the answer to the question as to the origin of the pleurisy set forth in the preceding paragraphs.

Acute idiopathic pleurisy from exposure to cold in a healthy subject is scarcely ever fatal. With moderate antiphlogistic treatment it is speedily relieved, and cured without leaving sequelæ behind. Even when neglected, and when one side of the chest has been allowed to fill with serum, it is remarkable how well such cases do after aspiration.

An effusion which half fills the pleura without pain or fever, and is only discovered by physical examination in search of a cause for the patient's dyspnœa,—this should make one suspect tubercle or Bright's disease. But when these can both be negatived, the prognosis still is good.

* See on this subject a paper by Dr Barrs, of Leeds ('Brit. Med. Journ.,' 1890, i, 1058).

To leave a patient, however, with one side of the chest full of fluid is never safe. He may die suddenly from syncope, or œdema of the other lung may suffocate him before help can be brought.

The pleurisy which forms part of acute pneumonia adds to the pain, but not to the danger of the primary disease; and the same is true when pleurisy is secondary to lymphoma, or other mediastinal growths. In the latter case it is usually latent, and often as much dropsical as inflammatory.

Tubercular pleurisy does not usually add to the dangers of phthisis, and often appears to retard its progress by limiting the amount of blood as well as of air in the diseased lung, for caseous inflammation does not flourish in anæmic and airless pulmonary tissues. As we have stated above, the effect of carnification on miliary tuberculosis is uncertain. On the other hand, pleurisy secondary to Bright's disease, whether dry or combined with hydrothorax, is a very serious complication, only less so than the pericarditis which often supervenes under the same circumstances.

When pleuritic effusion is purulent, the prognosis is more grave. Formerly the event was often fatal, by pyæmia, by hectic fever, by secondary tubercular phthisis, or by lardaceous disease; and in the best cases much deformity was the usual result, as described above (p. 1030).

But the bolder treatment on which modern surgery safely ventures, has wonderfully improved the prognosis of empyema. In the case of children a single free opening made and a drainage-tube inserted has repeatedly been followed by re-expansion of the lung and complete recovery, without the least sign of the disease remaining except the scar of the operation. With adults the result is not so often perfect, but here also complete cures are not infrequent, and complete failure is the exception.

Treatment.—It is evident from the facts above stated that the treatment of pleurisy is of great importance. There are cases which, left to themselves, run a course as favourable as could be desired. There are others which, even if they do not end fatally, leave the patient crippled and deformed, worn out and emaciated by the drain of a purulent discharge, or the victim of an incurable affection of the kidneys or intestine.

Except in the mild adhesive form of the disease, a person affected with pleurisy should be kept strictly in bed during the early stage. For the relief of pain, the application of a blister is perhaps more generally serviceable than anything else, and it may be used with advantage at any period. But many physicians hold that for prompt and grateful relief of the acute pain, as well as of the dyspnœa, no remedy is so efficacious as the application of half a dozen leeches to the side. Among milder measures, such as poulticing and the application of belladonna, none are so effectual as careful bandaging of the affected side, so as to restrain its movement in respiration.

Of drugs, those most commonly prescribed when effusion has taken place are purgatives, diuretics (such as digitalis, acetate, iodide, citrate, and nitrate of potass), and mercurial liniment externally. Marked results have followed the application of mercurial ointment, a rub which had been heard day after day for weeks ceasing almost at once, or fluid effusion clearing away after a somewhat longer period. The diet should be light and spare. The plan of allowing the patient very little to drink was often practised at Guy's Hospital by Sir William Gull and by Dr Moxon, and is advocated by Niemeyer. Fräntzel remarks that a very rapid absorption of fluids from the chest has been noticed when the patient has been attacked by cholera;

and the writer has seen the same result from an attack of summer diarrhœa. As a rule, it is better to act on the kidneys than on the skin or the bowels.

Paracentesis thoracis.—Whenever the physical signs indicate that there is considerable liquid effusion into the pleural cavity, the question of removing it by tapping must be carefully considered. This procedure, it is interesting to know, dates back to Hippocrates. But although Trousseau advocated it as far back as 1843, and Hughes as strongly in 1844, few physicians, until twenty years later, understood its importance or safety.*

There is still difference of opinion as to how soon the operation should be undertaken. Trousseau used to tap early and frequently, but if as soon as the signs of fluid in the pleura were recognised, paracentesis were performed, "dry tapping" would be much more common and the results less satisfactory. The best practice seems to be first to try to procure absorption of the effused serum by diuretics and laxatives.

If percussion shows that the quantity of fluid is moderate, it is as a rule advisable to wait. The presence of pyrexia is, at an early stage of pleurisy, a reason for delay. The patient must be watched very closely, to see whether the effusion increases or diminishes as time goes on. Unless it begins to diminish in the course of a fortnight, no further postponement of tapping is desirable. For, even though the quantity of liquid should remain unaltered, the probability that the lung will quickly expand and regain its functions after paracentesis will become less and less, in proportion to the length of time during which it has been compressed; for the layers of lymph that bind it down have been allowed to become fibrous and to contract. Moreover, the withdrawal of a part of the fluid by operation seems often to facilitate the absorption of the rest; it is supposed that the subpleural lymph-channels are mechanically pressed upon by the liquid, and that the flow through them is interfered with; but the same good effect sometimes follows a dry tapping.

We may safely delay with a patient in a hospital ward watched day and night, and with immediate assistance at hand, when it would be imprudent to leave fluid in the chest of one living at a distance from medical aid. In cases of Bright's disease when one lung is half carnified by fluid, paracentesis should be performed at once, or sudden œdema of the other may prove fatal before help can come.

In any case, if percussion shows that one side of the chest is full of fluid, the operation cannot safely be delayed (p. 1028) even until the following day; and this in spite of the absence of obvious distress of breathing, or the presence of pyrexia.

Whenever we have reason to believe empyema to be present by the signs and probabilities mentioned above (p. 1032), we should aspirate at once. As Kussmaul stated in the 'Deutsches Archiv' for 1868, if there be pus in the pleural cavity, its removal is often followed by the cessation of pyrexia.†

* A paper by the late Dr Hughes and Mr Cock recording twenty cases of pleuritic effusion treated by paracentesis appeared in the 'Guy's Reports' for 1844.

† Of this I saw a most striking instance in 1881 in a man who had pleurisy as a sequel of enteric fever. His temperature rose every afternoon to between 102° and 103°, falling in the night and morning. I had made one unsuccessful attempt to draw off the effused fluid, the reason of my failure being that I used a very fine aspirator needle, because the area of percussion dulness was not in the usual position behind, but at the side of the chest, just outside the situation of the pericardium, so that I felt some hesitation in acting upon my diagnosis. However, six days later, when I visited him, I found him in a most critical condition, with great anxiety of face and with extreme distress of breathing. As

When it is decided to tap the chest, some physicians recommend that a preliminary puncture should be made by means of an empty hypodermic syringe, into the chamber of which some of the pleuritic liquid may be drawn. But it often happens that this procedure leads to no result, even though the diagnosis is correct. It has been recommended to fill the syringe with water first and inject a few drops first to ensure a result; but this plan does not always succeed, and may lead to septic contamination. On the whole, the use of the instrument seems to be undesirable, at least when the condition of the patient is so serious as to make the removal of the effusion a matter of importance. For either liquid enters the syringe or it does not. In the former case a larger trocar is at once employed, and the patient might as well have been saved the slight pain of the preliminary puncture. In the latter case one is very much hampered in taking any further step, which is yet perhaps essential to his safety.

The operation has been much facilitated by the introduction of Dieulafoy's aspirator. Its use is greatly to be preferred to an ordinary trocar for paracentesis of the chest, for through a trocar fluid will only escape from the pleural cavity when the pressure there is greater than the atmospheric pressure. Several pints may be present, and yet sometimes there may be only a momentary flow of it during the act of expiration, or when the patient happens to cough. Moreover, there is great danger of air being sucked back into the pleural space by a deep inspiration.*

Even when the aspirator is used, there is often difficulty in getting out any considerable quantity of the liquid. Pieces of lymph are drawn against the inner orifice of the tube, or its channel may be occluded by viscid or curdy pus. Sometimes one can restore the flow by moving the cannula in various directions. If this fails, it may be necessary to withdraw it and to make a second puncture at a different spot. It should be a rule without exception never to employ for tapping the chest the hollow needles which are commonly sold with the aspiratory apparatus. One expects the lung to be expanded as the fluid is withdrawn, and there must be a very great risk of its being wounded if there be a sharp point in the way. A perfectly safe instrument consists of a trocar, and a cannula with a lateral opening, to which the tube of the aspirator is fitted; there is also a stopcock which can be turned at the moment when the trocar, having

the only chance of saving his life I had a somewhat larger trocar plunged into the chest at exactly the same spot as before. Aspiration was then performed, but at first no fluid appeared. However, I took the instrument and pushed it inwards, feeling, as I did this, that the end of it encountered and seemed to pass through a resisting membrane. A quantity of rather viscid blood-stained liquid at once escaped, and of this four and a half ounces were withdrawn. The patient was instantly relieved, and from that time went on to recovery without a bad symptom. His temperature, which was rising at the time of the operation and had reached 100·8°, fell from that very moment; three hours later it was normal, and during the next three days it only once reached 99·4°.—C. H. F.

* Some of those who advocate the operation maintain that the introduction of air is a matter of but little importance, on the ground (which cannot be denied) that it has often occurred without ill effects. But few surgeons would deny that it must involve the risk of giving a septic character to the inflammatory process. However, one can prevent it by surrounding the mouth of the trocar with a piece of moistened gold-beater's skin, which acts as a valve; or, as has been usual in England, one can fit on an elastic tube and make it dip beneath the surface of water containing carbolic acid, in a basin on the floor.

In tapping the chest for simple pleuritic effusion Mr Davies-Colley thinks the best plan is, after introducing the cannula, to attach a long rubber tube to it, and to evacuate the cavity by means of the siphon-action exerted by the fluid in the pendent tube. If a stoppage occurs in the flow, the aspirator may be used to remove it, but otherwise it is better to avoid the strong suction of this instrument, as it may give rise to hæmorrhage.

punctured the chest, is being withdrawn. Another advantage of this instrument is, that should the cannula become obstructed, a blunt probe can be passed in to clear it, without having to detach the aspirator-tube.

The best spot for puncturing the chest is generally said to be about two inches outside the edge of the pectoralis major, and just above the edge of the sixth rib on the left side or of the fifth rib on the right side. At Guy's Hospital it has been usual to select a lower intercostal space, and a point much nearer to the posterior fold of the axilla—the seventh space just outside the angle of the scapula. Bowditch recommended that the instrument should be introduced between the ninth and the eleventh ribs. Whichever space is chosen, we should keep close to the upper edge of a rib in order not to wound the intercostal artery. In 1855 this accident happened during an operation performed at Guy's Hospital; the patient (who had phthisis) became faint at the time, and died the same evening; a pound of clotted blood was found in the base of the chest. Fräntzel speaks of the use of a "capillary" trocar as obviating all risk of such an occurrence; but instances of it are very rare, and from the difficulty of extracting the fluid in many cases, it is injudicious to employ too small an instrument.

It is not desirable, in performing paracentesis, to attempt to empty the pleural cavity. Not more than from one to three pints should be withdrawn at once. In many cases, during the operation or immediately afterwards, paroxysms of cough occur, which are best relieved by a hypodermic injection of morphia.* It is easy to see that the increased activity of circulation in the pulmonary vessels, which must be one result of the operation, may lead to the giving way of any weak spot in their walls; and hæmoptysis is not a very rare effect of paracentesis.

A more frequent occurrence is œdema of the pulmonary tissue on the affected side. This seems to be the cause of a phenomenon which attracted much attention in Paris several years ago—the expectoration after thoracocentesis of large quantities of a frothy liquid containing much albumen. The patient to whom this accident happens may have experienced the usual relief from the operation; but after an interval of from ten minutes to an hour his breathing becomes distressed, he begins to cough, and he may turn livid, and die in a quarter of an hour. Twenty-one instances of it were collected by Terrillon in a monograph published in 1873; most of them, however, ended in recovery, and some were comparatively slight. The close resemblance between the fluid discharged from the air-passages in such cases and that withdrawn by the trocar so short a time before seems to have led some distinguished French observers to suppose that the expectorated albumen was dependent upon the presence of a communication between the cavity of the pleura and the interior of the lung, their notion being either that the lung was wounded during the thoracocentesis or that a perforation existed previously, which became opened out

* As Fräntzel remarks, cough is probably set up by the re-entry of air into the tubes of the lung which had been compressed, or it may be from irritation of the surface of the lung by the cannula. That it is not always due to the latter cause is shown by its being sometimes produced when the quantity of fluid is still so great that such contact cannot have taken place. Moreover, he has repeatedly felt the orifice of the instrument rest against the pulmonary pleura without any cough resulting. Since he has used the aspirator, and drawn off pleuritic effusion very slowly, he has very seldom observed these severe fits of coughing. That they are not always due to expansion of the lung seems probable by their sometimes occurring in cases of empyema with old adhesions.

as the pressure was removed from the surface of the organ. But, as Terrillon had no difficulty in showing, such opinions are quite untenable, and the only reasonable explanation is that there is suddenly produced an active hyperæmia, which leads to œdema of the pulmonary tissue.

Among the objections that have been urged against the performance of thoracocentesis, except in cases of absolute necessity, one, which had the support of Dr Stokes, of Dublin, and of Sir Thomas Watson, is that it may lead to the conversion into pus of an effusion originally sero-fibrinous. And although this suggestion is rejected by Trousseau, there is probably truth in it. Nothing is more likely than that the vessels in an inflamed pleura are often weakened and dilated to such an extent that a sudden and great removal of pressure from them may cause increased exudation. And in some cases in which a clear fluid is withdrawn at a first operation pus appears on the second or third occasion, even when there is no reason to believe that air has entered, or that the instrument was not scrupulously clean. Thus, although it accords with the natural tendency of the disease, that as it advances the proportion of leucocytes in the exudation should become greater, one cannot but admit that this process may sometimes be hastened by the performance of an operation.*

In certain cases the fluid quickly accumulates again after paracentesis, so that the patient's condition becomes as bad as before, and the operation has to be repeated. When this happens two or three times in succession, perhaps at intervals of only a few days, Fräntzel advises that one should desist from further interference, which will only precipitate the downward course of the case. But this is not the writer's experience in the case of a girl, a patient of Mr Lacey, of Woolwich, who was tapped fourteen times for hydrothorax in the course of mitral disease, sometimes at intervals of only a very few days, and yet recovered.

Paracentesis in empyema.—If the fluid obtained by paracentesis is purulent, the further treatment requires to be modified. One plan is to withdraw as much of the pus as possible, and then to close the puncture with lint and plaster, for sometimes what remains of the effusion undergoes absorption. Cheesy masses, and even thick, hard deposits of calcareous matter, are now and then found after death lying between adherent pleural surfaces; and there can be little doubt that such residues have usually, if not always, had their origin in an empyema. In other cases a collection of liquid pus, enclosed in a dense capsule, has been discovered in the pleural cavity, when death was due to another cause. Dr Moxon cites such an instance, in which there was a history of pleurisy three years before, and in which physical signs of fluid in the chest had been observed during the intervening period. But in most cases the effusion quickly reaccumulates, a second operation is required, and after this a third. Each time adhesions may possibly form between the opposed surfaces of the pleura, so as to narrow the cavity; but a third operation should be an incision.

The other plan is to make a free incision as soon as the pus is seen flowing

* Fräntzel speaks of a burning pain in the seat of puncture and of an indefinite sense of pressure on the affected side as being generally present, and as lasting in some cases for a day or two. He also says that thoracocentesis is usually followed by a slight elevation of temperature, and that until the second, third, or fourth day a more or less considerable increase of effusion may be observed, after which a somewhat rapid process of absorption sets in, attended with diuresis. How such statements agree with the fact that an existing pyrexia is often suddenly cut short by the operation is not apparent. However this may be, there is no doubt that patients experience marked relief from the operation.

out, to put in a drainage-tube, and to allow the pus to escape into an antiseptic dressing, treating the empyema, in fact, as a large abscess: and this the present writer believes to be, as a rule, the safer as well as the more effectual practice.

In children we have sometimes attained excellent results by making an aperture just large enough to admit one end of a long elastic tube, of which the other end is carried beneath the surface of carbolised liquid in a jar placed beneath the bed. The elastic skin of a child grasps the tube firmly, and does not ulcerate. The negative pressure of the column of liquid, acting hydrostatically, seems gradually to raise the compressed lung. Within a short time the flow of pus may cease, and a permanent cure may be obtained. With older patients similar success is rare.

Injections of iodine, or of permanganate of potass, are often used to wash out the cavity at intervals of twenty-four or forty-eight hours. The incision should be made along the upper border of the rib, a short distance in front of the angle. A large tube should be introduced, and care should be taken to fix it in such a way that only a small portion of the tube enters the pleural cavity. In children it may be necessary to excise part of a rib to allow of the introduction of a sufficiently large tube.*

The operation of washing out the chest is not altogether free from danger. In 1876 Dr Cayley read before the Clinical Society a case which had occurred to him, and in which, while a solution of iodine was being injected, the patient suddenly became pale, unconscious, and convulsed; the temperature rose to 107°, and death followed in sixteen hours. He cites three cases recorded by French observers, in each of which like symptoms appeared, though one of them ended favourably. In 1874, at Guy's Hospital, a girl, aged sixteen, died in precisely the same way. She had had a drainage-tube inserted into the right chest for an empyema five weeks before, and was going on well. One day she was sitting up, and her chest was being washed out with carbolic acid, when she suddenly ceased to breathe, and, although artificial respiration was set in action, remained unconscious, with muscular twitchings, until death. Nothing has been found, on *post-mortem* examination, to account for such accidents. A suggestion that thrombi in the pulmonary veins may have been dislodged

* A somewhat different method is recommended by Fräntzel. Having, at the time of the operation, got rid of as much as possible of the pus, he pushes a long catheter downwards towards the spine, and slowly injects through it distilled water, at a temperature of 100° Fahr., until the space is full. He then draws off the water by another catheter with an exhausting syringe, and he repeats this procedure three or four times until what returns is quite clear. Masses of fibrin, sometimes as large as the palm of the hand, generally appear in the wound while this is being done, and are carefully removed. This is one of the advantages of Fräntzel's plan, for sometimes much trouble is caused at a later period by such masses, which may decompose. Finally, he fixes in the aperture a flat silver cannula, with a broad plate fitting upon the surface of the chest, of such a size that two catheters can be passed through it side by side; outside this are placed antiseptic dressings, and over them a bag of ice. Each day afterwards the pleural cavity is twice washed out by means of the catheters, of which one is introduced with great care to the farthest possible point, so as to prevent any accumulation of pus from taking place. He deems it important for the patient to lie in such a position that the wound is at a higher level than any part of the pleural space, so that the water may gravitate into every part. After two days a ½ per cent. solution of common salt is substituted; and later still a very dilute solution of iodine or of carbolic acid. Of eleven patients treated in this manner five were completely cured; five died, but most of them from causes which had little or nothing to do with the operation; one was under observation when Fräntzel wrote, and was doing well.

and have formed emboli in the heart or in the cerebral arteries seems to have been shown to be without foundation. It is noteworthy that in every one of the cases the chest had been washed out many times before without any ill effects occurring; the only difference being that in two instances a somewhat larger quantity of fluid was being injected than usual.

The process by which the sac of a discharging empyema becomes gradually obliterated seems to consist in the formation of granulation tissue, and in the union of the two opposed surfaces; in most cases this union probably begins at the root of the lung, and spreads from one point to another until it reaches the external orifice. Even before this has obliterated the cavity, absorption of any air in the pleura takes place by solution in the lymph of the serous membrane, and, the wound being closed, the negative pressure in the pleura soon allows of the lung expanding if it is not bound down by adhesions. Fräntzel suggests, with much probability, that the compressed lung is re-inflated with air from the opposite lung during the act of coughing, or as the result of simple expiratory efforts with closed glottis.

The results of treatment of empyema by free incision and drainage, with modern methods and antiseptic precautions, are most encouraging. Even in adults one may again and again see complete recovery of the lung with no resulting deformity. In children the practice is still more successful. Thus Dr Goodhart reports that of 50 cases under Dr Frederick Taylor's care or his own 42 completely recovered, a sinus remained in 3, and only 5 died—1 from suppurative pericarditis, 1 from septic pneumonia, and 1 from measles and broncho-pneumonia.

In a certain number of cases the cure of an empyema remains incomplete. The cavity may have shrunk to very narrow dimensions, the chest may have regained a fair amount of resonance over a large part of its surface, air may enter the lungs pretty freely, but there is a fistulous opening from which small quantities of pus continually drain away. In such cases, and generally when other treatment has proved unsuccessful, it is now the practice to excise portions of one or more ribs, so as to allow the side of the chest to fall in and meet the lung. This operation seems to have been first performed by Dr Peitavy, and is now common.*

PNEUMOTHORAX.—Morgagni mentions the fact that air sometimes accumulates in the cavity of the pleura; but the word pneumothorax was first used in 1803 by Itard, and it was left for Laennec to give a full description of this affection.

Ætiology.—The older writers supposed that in exceptional cases gases form in the pleural cavity as the result of chemical decomposition or of liquid effusion, by direct secretion from the lining membrane. But this belief is unsupported by pathology or by experience; air is never found in the pleural space except when admitted from without.

* In the 'Birmingham Medical Review' for 1880 Dr William Thomas recorded several cases which were so treated, and in nearly all of them the result was highly satisfactory, the wound healing in a few weeks, and the lung re-expanding completely. The rib, too, was restored by a new growth of bone. It is to be observed, however, that the patients were all children under eight years old. In 1877 Mr Howse excised portions of three ribs from a child, aged six, a patient of Dr Taylor, in the Evelina Hospital, with results which are detailed in vol. xiii of the Clinical Society's 'Transactions.' Some improvement followed, but the cavity of the empyema did not close, and ultimately the child died with lardaceous organs. We have had numerous cases since, many successful; and sometimes the operation is absolutely necessary to give room for the drainage-tube. But it is better avoided when possible.

In the great majority of cases pneumothorax is a consequence of perforation of the *visceral layer* of the pleura, whereby air escapes from the lung. Often this arises from direct violence: broken ribs are exceedingly apt to wound the lung, and in persons who are run over or severely crushed the lung may be torn without there being any fracture of bone or laceration of the costal pleura. Exceptional instances of pneumothorax occur in medical practice in which a lung, previously healthy, is ruptured during a straining effort, or in a paroxysm of whooping-cough.* The fact that the bullæ of emphysema have often the thinnest conceivable walls might lead one to suppose that pneumothorax would occasionally arise from their rupture. But this (if it ever happens) must be exceedingly rare.

Occasionally the entrance of air into the pleural space is the result of local ulceration or sloughing of the pulmonary pleura. Sometimes, though very seldom, the disease is acute pneumonia running on to gangrene. Much more often it is a slough, dependent upon infective embolism in the case of pyæmia. Sometimes it is sacculated dilatations of the bronchial tubes which open into the pleura. But such cases are extremely rare.

The only common cause of pneumothorax is the rupture of a superficial vomica in phthisis. Walshe estimates that nine out of ten cases arise in this way, and Fräntzel puts it at fourteen to one. It would occur much oftener than it does but for the adhesive pleurisy, which accompanies chronic phthisis and generally seals up the pleural cavity. Even when there is no evidence of phthisis either before or afterwards, it is a question whether the spontaneous development of pneumothorax, without any previous violent muscular effort, is not due to the rupture of a small vomica, by which neither physical signs nor symptoms have been produced.

The following case was related by Prof. Vogel, of Dorpat, in the second volume of the 'Deutsches Archiv.' A woman, aged twenty-nine, became suddenly the subject of pneumothorax one morning at nine o'clock. Some months previously she had a slight loose cough, and more recently a little pricking pain in the region of the liver; when the attack began she was engaged in turning over her child's bed, and just before she had been lifting its bath. Vogel himself was inclined to think that she had latent tubercular disease, but in four weeks she recovered completely.

Another way in which pneumothorax may arise is from perforation of the visceral pleura by an empyema discharging itself through the air-passages. In medical practice this cause comes next to phthisis in frequency. Possibly pleurisy may give rise to pneumothorax at an earlier stage, if the inflammation is sufficiently intense to lead to sloughing of the visceral layer of the membrane. Thus in 1869 a man, aged forty-two, was brought into Guy's Hospital very ill, and died half an hour after. He was found to have acute pericarditis, mediastinal inflammation, and early pleurisy on the left side. But the principal seat of disease was the right pleural cavity. This contained fœtid gas, and four and a half pints of dirty purulent fluid. In the upper lobe of the lung there were two openings, and through these air had doubtless entered. But the pulmonary pleura was gangrenous over an area of two square inches, and the substance of the lung beneath it to a

* Fräntzel relates in 'Ziemssen's Handbuch' how a youth of nineteen, who was exerting all his strength to push a heavy cask, felt something give way in his chest, and became suddenly short of breath and powerless. As he recovered in six weeks, without any pulmonary disease being discovered, it may probably be assumed that none had existed before.

depth of half an inch. That the pleurisy was of exceptional severity was evident from the fact that there was suppuration outside its parietal layer, among the intercostal muscles.

There still remain cases in which the air is not derived from the lung at all, but either from the outside of the chest, or from some part of the alimentary canal. As a consequence of perforation of the thoracic walls (apart from the effect of penetrating wounds of the chest), pneumothorax may be seen by physicians when an empyema has broken through spontaneously, or has been let out by operation. When the pus points of its own accord, the channel by which it reaches the surface is commonly oblique and indirect, so that air fails to find its way along it. Dr Moxon drew attention to the possible occurrence of double pneumothorax as a cause of death after tracheotomy, subcutaneous emphysema extending down from the wound so as to fill the mediastinal connective tissue with air, which then bursts into both pleural cavities. One such case occurred in a woman, aged thirty-three, who died in less than twenty-four hours after the operation. Emphysema had spread over the neck, chest, and arms as far as the fingers. Both lungs were found collapsed and almost airless.

The part of the alimentary canal which is most often the starting-point of pneumothorax is the œsophagus; a malignant growth may eat its way into the pleural cavity, or the ulceration due to a foreign body may have a like result. But sometimes a gastric ulcer, after setting up a circumscribed hypophrenic abscess, has led to perforation of the diaphragm; and a hydatid cyst of the liver has been known to open communications in two opposite directions, with the bowel below, and with the pleural space above.

Physical causes of pneumothorax.—Few hospital physicians can have failed to meet with cases difficult to explain, in which communication of the pleura with the outer air, through the parietes of the chest or through the lung, has not been followed by pneumothorax. In most cases pleural adhesions, at or in the near neighbourhood of the perforation, afford a probable account of the difficulty, and their presence has been confirmed after the patient's death. But certain cases seem incapable of this explanation. In a lecture reported in the 'British Medical Journal' for June 4th, 1887, Dr Goodhart —after referring to the fact that pleuritic effusion may be "held up," so to speak, over the lung instead of all gravitating to the bottom of the chest (cf. p. 1022)—proceeds to comment on the rarity of pneumothorax after fracture of the ribs, particularly in young patients, and on the free re-expansion of the lung, even after a large opening has been made into the chest by paracentesis, and seems to think that there must be some forces at work to allow of the lung becoming inflated again by inspiration different from those known to physics. Mr Godlee replied in a subsequent number of the same journal from the surgical point of view, arguing the expediency of excision of the ribs in the treatment of empyema.

The subject was dealt with by Dr Samuel West in his interesting Bradshaw Lecture before the College of Physicians (*ibid.*, August, 1887). He showed experimentally that there is considerable power of cohesion between opposed surfaces of serous membrane, and attributed to this cause the fact that pneumothorax does not occur so readily as one might have supposed.

There can be no doubt in the mind of any physiologist who has seen the unfailing and immediate collapse of the lungs which follows a free incision into the pleura in the case of an animal, that when the pressure on the inside and outside of the lung is equal, it at once shrinks to the bulk

which the elasticity of its tissue permits. This is proved experimentally by Donder's "schema," and by a similar arrangement of the dead thorax with manometers to gauge the pressure. The terrible result of tapping a healthy pleura when the other lung is incapable of expansion confirms the conclusion derived from more frequent and harmless experiments.

Apart from any mechanical obstacle to separation of the two layers of pleura, either from adhesions or from their natural cohesion, it is obvious that when a pleuritic effusion is tapped and runs out, the intra-thoracic pressure must be greater than the barometric pressure of the air at the time. When it becomes greater with expiration, the pus or serum runs with a jerk; when it lessens with inspiration, the flow lessens also; when the pressure on the chest becomes negative, the flow ceases; or, if there is not enough fluid to close the trocar, air is sucked in. But when the orifice is closed, after a little air has been admitted no more will enter, and that already in the pleura will be quickly dissolved by the remaining fluid, or will be absorbed by the lymphatics of the pleura—first the oxygen, then the nitrogen and carbonic dioxide. As the air is thus absorbed, the pressure in the pleura diminishes, and the lung again expands. Even if a large opening is made the lung is not emptied of air; it is only reduced to the condition observed after the thorax is opened, after death from some disease which has not affected the thorax. There is no carnified (*i. e.* completely airless) lung to be re-expanded, unless pleuritic effusion has compressed it for a long time. As soon as the pressure on its surface becomes a little less than that in the trachea the compressed lung will begin to expand again, if not mechanically prevented by thick adhesions.

Anatomy.—The recognition of pneumothorax is not always a perfectly simple matter, even in the dead body. In making an autopsy, at the moment when the knife is first plunged into the thorax, the air can sometimes be heard to rush out; or, if a puncture is made with a trocar, it may escape in a jet, so as to blow out a lighted match. But this occurs only when its pressure is greater than that of the atmosphere, which is by no means generally the case. In all probability the existence of air in the pleural space is very often overlooked in ordinary *post-mortem* examinations, especially in the bodies of phthisical patients, in whom, from the presence of extensive adhesions, the collapse of the lung has been only partial. The best way of making sure whether there is pneumothorax or not is to puncture the chest under water, which may be done either by dissecting off the tissues from the ribs, so as to form a pouch that can be filled with water, or by pouring water into the abdomen, and then perforating the diaphragm with a trocar. If pleuritic effusion is present, it is sufficient to shake the body before opening the chest; then, if there is any air, the liquid will be frothy.

When the pneumothorax arises from perforation of the visceral pleura, the aperture by which the air entered is sometimes plainly visible; it may be as large as a threepenny-piece. More often it is covered by recently formed lymph, and the only way of detecting it is to inflate the lung with bellows through the trachea. Or it may have become completely closed by adhesions during the interval between the occurrence of the pneumothorax and the death of the patient, so that there is no possibility of discovering it. It is most commonly situated upon the lateral surface of the lung, in the upper lobe near its lower border, or in the lower lobe near its upper border.

The chemical nature of air withdrawn from the pleural space was inves-

tigated by Dr John Davy many years ago,* and analyses have since been made by other chemists; it has always been found to consist mainly of nitrogen, and the amount of carbonic acid in it has generally been greater than that of the oxygen; sulphuretted hydrogen has been present when the other contents of the cavity were putrid. Dr Walshe explains the difference of this pleural air from that of the atmospheric by the fact that it traversed the lung before reaching the pleura. But it can hardly be said to have passed through pulmonary tissue, and, moreover, its composition is far more altered than that of normally expired air. Obviously, therefore, it must have undergone change while in the pleural space, either from the solvent action of the liquid effusion, or from absorption by the pleural membrane—*i. e.* by the lymph which fills its stomata and lymphatics, and by the subpleural veins.

The secondary pleurisy.—When death occurs within a few hours after the development of pneumothorax, the cavity of the pleura is of course found empty, there having been no time for the occurrence of effusion. But in other cases, at least such as are seen by physicians, an empyema is, as a rule, formed in a few days. Dr Walshe has discovered signs of liquid effusion within twenty-four hours. A striking instance to the contrary is afforded by Vogel's case, already quoted (p. 1043). He repeatedly examined his patient during the month after she was attacked, and could never detect the slightest indication of pleurisy.

There is no doubt that the power of the air to set up suppuration depends upon its containing septic microbes. But, as we have seen, pneumothorax is, in most cases, due to the rupture of a phthisical vomica into the pleural space. The contents of the vomica must generally escape with the air, and they are probably the cause of the pleurisy which follows. When the original affection is a sloughing block in the lung, or when the pleura is perforated by a malignant œsophageal growth, or by a hypophrenic abscess communicating with the stomach, the consequent inflammation is peculiarly severe and rapid in its course.† On the other hand, in surgical practice, when a healthy lung is wounded by fractured ribs, we are told that pleurisy is often absent. Probably very much depends upon whether or not the aperture in the lung becomes quickly closed again; for the risk of the entrance of germs must be greatly diminished if no air is admitted beyond that which immediately fills the serous cavity.

It is clearly impossible for subcutaneous emphysema to be produced by fracture of the ribs without there being also pneumothorax, unless the pleural space at the seat of injury happens to have been closed by former adhesions. But in cases of this kind we have often failed to detect any signs of the presence of air in the serous cavity when a day or two had passed before an opportunity of examining the patient was afforded. So that air must often be absorbed very rapidly from the pleural space; and this conclusion is quite in accordance with the results of experiments on animals. Cohnheim says that in rabbits it is not possible by injection of air into the pleura to cause compression of the lung so as to study the effects of pneumothorax, because the air is so quickly absorbed.

Locality.—Dr Walshe states that of eighty-seven cases of perforation

* 'Phil. Trans.,' 1823; and in his collected 'Researches,' vol. ii, p. 249.

† Of this we have recently had an instance (June, 1890) in a patient with extensive sero-purulent effusion on the right side caused by a sloughing abscess perforating the diaphragm, which originated in cancer of the stomach.

of a tuberculous lung collected by him from various sources, fifty-five affected the left and thirty-two the right pleura. But among twenty-six cases of pneumothorax taken from the records of Guy's Hospital without selection, the number on each side of the chest was exactly equal.

Physical signs.—Whether pneumothorax is easy or difficult of diagnosis, depends upon a variety of circumstances. Its recognition must always be the result of physical examination of the chest, although the patient's symptoms, and the way in which they develop themselves, often enable one to guess the nature of the case.

In general, pneumothorax is to be suspected whenever, over a large part of the chest, but on one side only, marked deficiency of vesicular murmur is associated with tympanitic resonance on percussion.

Enfeeblement or *absence of vesicular murmur* is a very important indication; and sometimes the faint sound which accompanies the breathing gives one an impression of being conveyed from a distant part of the chest. But in many cases there is marked *amphoric breathing.* Sometimes, no doubt, this is due directly to the passage of air backwards and forwards into the pleural cavity; but it is often present when the aperture is closed, and when, as Dr Gee remarks, it must acquire its peculiar quality by transmission through the pneumothorax.

The *voice* may either be less audible than on the healthy side, or it may be conveyed so as to produce bronchophony or even pectoriloquy. As a rule, *vocal fremitus* is either absent or greatly diminished.

The *percussion-note* is altered in the direction of over-resonance, with, as a rule, a tympanitic quality. When air escapes into a healthy pleural sac the sound is, as a rule, musically clear and resounding. But if the air should accumulate so as to cause extreme distension, it may, in the words of Dr Walshe, at length become "muffled, toneless, almost dull," like that of a drum tightened to the highest possible point, and with all escape of air from its cavity prevented. More frequently, the reason why the percussion-sound in pneumothorax is imperfectly resonant is that the pleura itself is thickened; in all probability not only do the chest-walls themselves fail to vibrate, but they are incapable of transmitting the percussion-note to the air within, so as to throw it into free vibration. In such cases one may obtain any one of the modifications of percussion-sound mentioned at p. 930 —osteal, tracheal, or subtympanitic.

Metallic sounds.—There still remain certain physical signs, which when present are striking and characteristic, although their absence is no argument against the existence of pneumothorax. They may be grouped together as "metallic" sounds.

Laennec described *metallic tinkling** as a sound like that "produced in a metal cup, or in one made of glass or of porcelain, by gently striking it with a pin, or by dropping into it a grain of sand." He described it as being heard when the patient either breathed, or spoke, or coughed. There was afterwards much discussion as to the origin of this sound, but there is now general agreement that it is caused by the bursting of bubbles of fluid in a large space, which is filled with air and has a smooth surface. In other words, metallic tinkling is a moist sound, or râle, modified by the vibrations of the walls of a large air-containing cavity. One way in which the bubbling necessary to give rise to such a sound may be produced was noticed by Laennec himself; namely, by the

* *Fr.* Tintement métallique.—*Germ.* Metallklang.

dropping of liquid from the upper into the lower part of the pleural space when it contains air as well as pus. Thus metallic tinkling may be due to the patient's changing from the recumbent to the sitting posture; but one is hardly likely to hear this unless one has the stethoscope applied to his chest before he begins to move. Again, there is no difficulty in understanding how the sign may be produced by coughing, as well as by drawing in the breath, especially if there be a free communication between the space in which it is found and a bronchus.

True metallic tinkling does not seem to arise as a mere result of speaking. What is then heard is rather an *echo* of the voice, which acquires a metallic quality from the conditions under which it is produced. So also the heart-sounds, and even the sound produced by percussion of the chest, may be reverberated with a similar musical quality. The thin, clear "tick-tack" of the heart in pneumothorax is like the sound of a watch or a child's "musical cart," and is a most characteristic sign. To these phenomena it would be well to give the name of "metallic echo;" reserving that of "metallic tinkling" for sounds which in their origin resemble râles. Coughing may be attended either with echo, or with tinkling.

A particular kind of metallic echo was described by Trousseau as *le bruit d'airain*. Among all the "metallic" signs it has the advantage of being completely under the control of the observer. Metallic tinkling is well known to be exceedingly capricious, accompanying certain respiratory movements and being absent with others, according as bubbles happen or do not happen to burst. Even a metallic echo of the patient's voice may probably fail to be heard unless he speaks distinctly and with a certain pitch and loudness. But the *bruit d'airain* can not only be determined as to the time, but the sound which is to produce it can be varied, until one obtains the best possible result. The method of eliciting it was originally given in the 'Gazette des Hôpitaux' for 1859. It consists in applying one's ear to the back of the patient's chest, while a third person strikes the front of the chest, either with the hammer upon the plessimeter, or with one coin upon another. The metallic echo which results is sometimes wonderfully distinct, and there are probably few cases of pneumothorax in which it is absent. One may sometimes, however, fail to obtain a "bell-sound" by percussion during life, and yet have no difficulty in eliciting it from the dead body of the same patient. Traube attributes this fact to lowering of the tension of the air in the pleural space, as the result of cooling of the tissues after death.

Another sign of pneumothorax, which is of great historical interest, is termed the *succussion-splash*. It was well known to Hippocrates, so that it is sometimes spoken of as "Hippocratic succussion."* To obtain it, one may shake the patient's body while one has one's head pressed against his chest. But sometimes it can be heard at a little distance off,

* "Another malady. When the time grows long [after an inflammation of the chest has appeared], then the fever becomes higher and the cough increases, and the patient's side pains him, and he can no longer bear to lie on the sound side but only on the diseased one, and his feet swell and the hollow of his eyes. Then, when fifteen days have elapsed since the rupture [*i. e.* the bursting of an abscess into the pleura as the result of peripneumony, for that was the Hippocratic pathology of empyema], give the patient a warm bath [or, possibly, bathe the affected side with hot water] and set him upon a good steady stool. Then, while a friend holds his hands, do you shake him by the shoulder and listen, so as to tell on which side of the chest there is a splash (ψοφέῃ). [The word ψόφος denotes a noise, *strepitus*, as opposed to a musical or an articulate sound: it is applied to doors banging, armour clanging, and streams splashing.]"—Hipp., 'De Morbis,' lib. ii, cap. xvi.

and the patient himself may be conscious of it every time he makes any abrupt movement, as in stepping downstairs, or in riding on horseback. It is literally nothing else than the splashing of pleuritic effusion against the sides of the serous cavity, and of course it is never audible unless there is liquid present as well as air.

In such cases, accordingly, the signs of pleuritic effusion are to be observed, as well as those of pneumothorax; it may also be noted that alterations of the level of dulness when the patient changes his posture are generally very conspicuous, whereas in uncomplicated pleurisy they can seldom be made out satisfactorily (cf. p. 1022).

Dislocation of viscera.—In most instances pneumothorax is attended with lateral displacement of the heart. Dr Douglas Powell showed in vol. lix of the 'Med.-Chir. Trans.' that the mere elasticity of the opposite lung drags the mediastinum over whenever air has free entrance into one pleural space, without there being of necessity any excess of pressure above that of the atmosphere. He remarks, however, that, in some cases of phthisis, consolidation of the lung on the side opposite to the pneumothorax prevents the mediastinum from being thus displaced; and probably a like effect is also produced by consolidation and adhesion of any considerable part of the lung on the side of the pleural affection, or, again, by the rigidity and thickening of the pleura, which so often occur in cases of empyema before perforation takes place. Thus one must not expect to find the heart beating in an abnormal position in those cases of chronic disease of the chest in which it is sometimes so difficult to determine whether pneumothorax is or is not present.

Even in such cases it is possible for the pressure of the air in the pleural cavity to be considerably increased. The way in which this is brought about is by the action of a piece of false membrane lying over the aperture; this plays the part of a valve, and allows air to enter the cavity during inspiration, but hinders its escape during expiration. Cohnheim, indeed, declares that for air confined in the pleural space to retain for any length of time a high pressure after closure of the opening by which it entered is impossible, on account of the rapidity with which it undergoes absorption. But it is certain that among 17 cases collected by Dr Powell there were 12 in which, after death, the pressure was found to be above the atmospheric pressure, the difference amounting in these cases to that of a column of from five and a half to seven inches of water. When the adjacent organs are capable of yielding to it, one cannot be surprised that the elastic force exerted by air in the pleural cavity should displace them even more than they are displaced by liquid effusion. Thus Dr Gee speaks of the diaphragm as being pushed down so that the upper surface of the liver lies below the level of the anterior costal margin, and percussion yields a tympanitic sound in the right hypochondrium. The intercostal spaces, too, may be flattened or bulging; and the affected side of the chest may be obviously enlarged as well as motionless.

Diagnosis.—There are few affections of which the physical signs may be mistaken for pneumothorax, or *vice versâ*.

The limitation of the signs to one side of the chest obviously suffices to exclude the possibility of their being due to emphysema, which from the time of Laennec has been given as the disease most needing distinction from pneumothorax; in practice the two are not in the least likely to be confounded.

When distension of the pleura with air is very extreme, the percussion-sound may become muffled and toneless; but this probably never reaches such a point that the case could be supposed to be one of liquid effusion.

In vol. xi of the 'St Bartholomew's Hospital Reports,' Mr Butlin has recorded an example of rupture of the diaphragm, with escape of the distended stomach and colon into the left pleural cavity; it was the result of a severe crush between the buffers of two railway coal-waggons, and was diagnosed during life as traumatic pneumothorax.

But in general the only cases which are attended with doubt are those in which, if air is present in the pleura at all, it is confined to a limited portion of the serous space. Thus at the upper part of the chest it might very likely be impossible to diagnose a localised pneumothorax from an exceedingly large vomica. It is doubtful, however, whether limited pneumothorax ever occurs in that position, and in all probability the cases that have been admitted as open to question have been really examples of vomicæ attended with unusual signs, such as metallic tinkling or Hippocratic succussion-splash. On the other hand, at the base of the chest, a cavity within the lung of sufficient size to be mistaken for pneumothorax is a thing almost, if not quite unknown.

It is possible that during the contraction of an empyema on the left side the diaphragm, with the stomach, may be drawn upwards so far that percussion may yield a tympanitic sound over a considerable area, where complete dulness might have been expected. A similar condition may also arise when the lung is affected with cirrhosis. Probably one might avoid an error of diagnosis by re-examining the patient after having made him swallow a large quantity of fluid. In a case of Wintrich's a subdiaphragmatic abscess, which arose from a perforating ulcer of the stomach, and consequently contained air, was mistaken for pneumothorax.

It is necessary to bear in mind the fact, mentioned at p. 990, that in some rare instances the percussion-note is tympanitic over part of a lung affected with pneumonic hepatisation. The other physical signs would negative the suspicion that there is air in the pleural cavity.

After all, the mistake which is most apt to be made in regard to pneumothorax is not that it is taken for any other affection or any other affection for it, but that its presence is overlooked. This is due to the fact that the symptoms of pneumothorax, though often of the most striking character, are sometimes altogether absent.

Symptoms.—The amount of dyspnœa produced by the escape of air into the pleural sac depends upon two conditions: first, upon whether the patient's vital functions are or are not being actively carried on at the time; and, secondly, upon whether he has or has not been accustomed to make full use of the lung on that side in breathing. A healthy person always experiences great distress when attacked with pneumothorax. Among those who are the subjects of disease the distress is greater in proportion as they are well nourished and able to take food and to bear exertion. It is also greater among those who have chronic pulmonary disease, in proportion as the lung on the side of the pneumothorax took a greater share of the work of respiration before the supervention of the accident. It accordingly reaches its maximum when a man who has one lung extensively diseased but whose health is nevertheless pretty good, becomes attacked with pneumothorax on the opposite side. A directly fatal result is then inevitable. Accordingly pneumothorax has to be remembered among the possible causes of sudden

death in persons who are walking about and earning their living. One morning, in the year 1874, there was brought into Guy's Hospital the body of a man who had fallen dead while on his way to his work; he was found to have pneumothorax on the right side, and chronic phthisis of the left lung.

On the other hand, if air escapes into the pleura of a person who is wasted, and whose functions are already at a low ebb, and especially if the lung on that side has before been rendered almost useless by advanced tubercular disease, the supervention of the pneumothorax may give rise to no symptoms whatever. This fact was stated in the 'Medical Gazette' for 1844, by Dr Hughes, who was one of the best auscultators of that day.

In persons who are in the last stage of phthisis, it is possible for pneumothorax to produce a shock that may be directly fatal, without any warning symptoms. The patient is perhaps found dead in bed, and nothing has occurred to attract the attention of the nurse.

Between the two extremes just described there are all degrees of severity in the symptoms of pneumothorax. The most typical cases are those in which the patient is suddenly seized with an agonising pain in the side, and has a sensation of something having given way or possibly of a stream of air or of water trickling down within his chest. His dyspnœa is extreme; the respirations may reach forty or even sixty in the minute, while the beats of the heart, although accelerated, are not so to any proportionate extent. The pulse is small, the radial arteries being imperfectly filled as a consequence of the deficient flow through the obstructed lungs. The hands, the feet, the cheeks, the lips, and the visible mucous membranes become cyanosed; the extremities and even the tongue feel cold; a cold sweat breaks out over the body; the temperature, even in the rectum, falls considerably. The voice is weak, or reduced to a whisper. There may be complete inability to cough. The patient is usually obliged to sit up in bed; sometimes he finds it more comfortable to incline towards the affected side, sometimes towards the healthy side.

Prognosis.—In some cases of pneumothorax the symptoms continue unabated until the death of the patient, which may take place after a few hours, or in a day or two. But in other cases they subside as the shock of the accident passes off; the breathing may remain rapid and yet the patient may experience little or no distress, as in a case in which Dr Walshe counted fifty-two respirations in the minute. In some very exceptional instances the air gradually undergoes absorption, and complete recovery takes place. Vogel's case, referred to at p. 1043, was one of these.

What usually happens is that after a few days pleurisy sets in. Even then it is not impossible for the disease to subside. Dr Walshe says that he has seen two cases in which in the course of two months all signs of air and fluid in the pleura disappeared; in all probability the exudation was sero-fibrinous. As a rule, when an empyema is developed, one can give the patient a chance of recovery only by making a free external opening, so as to allow the cavity to become obliterated by the process of granulation. The same treatment is of course necessary when the entrance of air into the pleura is secondary to pleurisy. But in cases in which there is already advanced phthisis it is scarcely ever right to perform such an operation, as the resulting inflammation of the pleural space is apt to assume a putrid character, and carry off the patient very rapidly. Nevertheless, Czernicki pointed out ('Gaz. hebd.,' 1872) that in some phthisical patients the supervention of pneumothorax with consequent spontaneous

pleuritic effusion actually leads to an improvement in the general symptoms and to cessation of expectoration, effects which can only be ascribed to anæmia of the affected lung, resulting from its collapse.

As a rule, death occurs within two or three weeks after perforation of the pleura. Traube insisted on the rapidity with which emaciation advances in many cases. Œdema of the limbs, and even of the face, sometimes develops itself; and the urine is sometimes albuminous.

On the other hand, it is surprising how long a pyo-pneumothorax may be tolerated, and how little discomfort it causes. The patient is sometimes able to take horse exercise, and thus, as already mentioned, may hear the fluid splashing within his chest while he is riding.

Traube relates a case of pneumothorax occurring in a woman who had been attacked by it some years before he first saw her, and in whom seven years later scarcely any physical signs were discoverable. She looked well, and could even walk uphill without discomfort. The history appeared to indicate that the affection arose as a complication of phthisis; for she had previously had a febrile illness, with night-sweats, cough, and hæmoptysis.

Treatment.—In cases of pneumothorax a great deal can be done to diminish the patient's sufferings, and perhaps to avert a fatal termination. Cupping, dry or wet, often gives remarkable relief, and venesection is probably still more efficacious. A small dose of morphia should be injected subcutaneously, or, as Dr Walshe recommends, a very little chloroform may be given by inhalation from time to time. He also says that he has seen musk in five-grain doses afford much relief.

If great enlargement of the side and depression of the diaphragm suggest that the pressure of air within the thorax is greater than the atmospheric pressure, paracentesis should be performed with a fine trocar. But displacement of the heart alone is not evidence of increased pressure; it may be due to the elasticity of the mediastinal tissues. Fräntzel appears to have tapped for pneumothorax rather frequently: he quotes a dissertation by Bärensprung, in which are recorded a number of cases treated in this way with success. He says that, if possible, it is well to postpone the operation until three or four days have elapsed, so that the aperture in the pleura which allowed the escape of the air may have closed. Between the fourth and the eighth day it may be advisable to introduce a trocar, even when the symptoms are not very urgent. He has often found the pressure of the air such that a considerable quantity passed out through the instrument; and, even when this is not the case, it is easy to close the wound, and no harm is done. An aspirator ought never to be employed, on account of the risk of reopening the original aperture. Fräntzel uses an ordinary trocar with a valve of goldbeater's skin (p. 1038, *note*). If cough arises during the operation, which is not uncommon, he either gives an injection of morphia, and waits for a time before withdrawing the trocar, or else he keeps up pressure upon the seat of puncture until the cough has ceased. By either of these methods the escape of air along the track of the trocar may be prevented, which would otherwise lead to subcutaneous emphysema.

PHTHISIS*

"While meagre Phthisis gives a silent blow,
Her strokes are sure, but her advances slow;
No loud alarms nor fierce assaults are shown;
She starves the fortress first, then takes the town."

ACUTE PULMONARY TUBERCULOSIS—*Distinction from phthisis—Morbid anatomy—Physical signs—Clinical symptoms and course—Diagnosis by concomitant tuberculosis, especially of the choroid—Ætiology—Prognosis.*

OF all diseases which attack adults, Phthisis or pulmonary Consumption is in our country, and in the temperate regions of Europe and America generally, by far the most fatal. It is estimated that a third of the deaths between fifteen and forty-five in England is due to this terrible disease.

From an early period in the history of medicine it has been known that progressive loss of flesh often accompanies cough, spitting of pus and blood, and other signs of disease of the lungs. This was distinguished as *phthisis pulmonum;* but the qualification was very early dropped, and in modern as well as ancient medicine phthisis or consumption means phthisis pulmonum, or pulmonary consumption. The term is now applied even to exceptional cases unattended with emaciation, but is never used when the lungs are believed to be healthy, even though wasting may be extreme.

There is, however, a secondary meaning of the word. Since it has been shown that most, if not all, cases of phthisis are tuberculous, such expressions as "renal phthisis," "intestinal phthisis," "laryngeal phthisis," have

* *Synonyms.*—Phthisis pulmonalis—Tabes pulmonum—Consumption of the lungs—Decline.—*Germ.* Lungenschwindsucht.—*Fr.* La phthisie. Φθίσις (from φθίνω, I waste = *tabes, consumptio*) occurs frequently in the Hippocratic writings, and there, as well as in those of Celsus and of Aretæus, means pulmonary phthisis. Celsus divides *Tabes* into Atrophy, Cachexia, and Phthisis. The earlier Greek physicians distinguished between Empyema, as suppuration outside, and Phthisis, as suppuration inside, the lung.

The following quotation from Celsus shows how good a clinical knowledge of the disease was formed by the Ancients:—"The third kind of decline (*tabes*) and by far the most dangerous is what the Greeks have named φθίσις. It usually arises from a cold in the head, whence it settles on the lungs, and there causes ulceration. There follows a slight feverish movement, which remits and comes again. There is a constant cough, raising of yellow matter, and sometimes of blood."

been introduced, to imply that the kidneys, the bowels, or the larynx present tuberculous lesions. But to make the clinical term phthisis synonymous with the histological term tuberculosis is most undesirable.

Pathology.—In proof of the extent to which opinions have differed as to the nature of phthisis, the words of Laennec in 1819 may be contrasted with those of Niemeyer in 1867. The former taught that "the existence of tubercles in the lungs is the cause, and constitutes the true anatomical character of consumption;" the latter, that in the majority of cases tubercles, if found in the lungs after death, "have been of recent origin, and have complicated the disease when it was already in an advanced stage." The older writer was, we may now affirm, undoubtedly right.

Phthisis one disease.—The appearances presented by the diseased lungs in cases of phthisis differ exceedingly; and its clinical symptoms and course are subject to no less wide variations. One cannot be surprised, therefore, that both pathologists and physicians have endeavoured to divide it into several diseases. Addison led the way in this direction by insisting that much of what was commonly regarded as tubercular disease in the lungs was in reality pneumonic, and that softening of the organ with excavation of its substance might occur without any tubercle being present; but he was very far from maintaining that an absolute distinction could be drawn. In his well-known essay, read before the Guy's Hospital Physical Society in 1845, he described first a "pneumonic" and then a "tuberculo-pneumonic phthisis;" and the final sentence of this work is, that "in every form of phthisis, inflammation constitutes the great instrument of destruction." Thus, after all, it may be said that Addison's teaching bore upon the question whether tubercles should be regarded as distinct from what Laennec used to term tubercular infiltration quite as much as upon the practical question whether a pneumonic kind of phthisis is to be recognised apart from the tubercular. Since his time other pathologists, particularly in Germany, have asserted in the most positive and dogmatic manner, that "catarrhal" or "caseous" pneumonia is the essential morbid change in many, if not in most, cases of phthisis. Another form which has also been declared non-tuberculous is the so-called "fibroid phthisis;" but there was never consensus of opinion among the most advanced pathologists with regard to these questions. Rindfleisch, who at one time maintained that the "tubercular granulations of Laennec" consisted in an inflammatory infiltration of the alveolar parenchyma round the smallest bronchi, afterwards admitted that they are true tubercles; and of late years the classical doctrine of Morton, Cullen, and Laennec is almost universally accepted, that phthisis is only one disease, and that it is always tubercular.

The varied appearances which may be found in the lungs after death depend mainly upon whether the tubercles and the tuberculous infiltration become caseous or undergo fibrous changes; and this, to a great extent, depends on the degree of rapidity with which the disease has advanced during life. Thus, pneumonic phthisis is generally equivalent to phthisis which has advanced quickly; fibroid phthisis to one of which the course has been very slow. No case of phthisis is without bronchitis and pleurisy, and few are without tubercular lesions elsewhere; but none are without the essential lesions of tubercle, catarrhal pneumonia, caseous degeneration, and more or less attempt at fibroid cicatrisation.

There is reason to believe that the tubercle bacillus (p. 312) is present in cases of phthisis of whatever form at some period of their course. In his earliest communication on the subject, Koch stated that he had found bacilli in twelve cases of caseous bronchitis with pneumonia; and these appear to have been all the examples of that variety of phthisis he had then examined. In fibroid phthisis one must look for them in the parts of the lungs most recently affected, and in the caseous form also they are generally limited to the edge of the infiltrated tissue. Sometimes nests of bacilli occur in the midst of infiltration. In tubercular vomicæ they are often present in great numbers. The little cheesy fragments, which are so commonly found in the cavities of phthisis, consist, according to Koch, almost entirely of masses of bacilli.*

Locality.—Phthisis affects both lungs. Clinically we constantly meet with early cases of consumption, in which the physical signs are confined to one side of the chest; but, as the disease advances, the opposite side becomes also involved. The evidence of autopsies proves that it is the rarest event for a patient to die of phthisis with one lung only affected. Nevertheless the disease is not perfectly symmetrical; it is almost always earlier and more advanced in one lung than in the other. It is much more symmetrical than pneumonia or pulmonary cirrhosis or pleurisy; rather more so than tubercular disease of the testes or adrenals, and less symmetrical than chronic tubal nephritis or than psoriasis.

It has long been known, both to physicians and to pathologists, that the upper parts of the lungs are almost invariably affected with phthisis, in whatever form, before the lower parts; and that in all but the most exceptional instances, the disease spreads downwards from apex to base, often with almost perfect regularity.

It is difficult to find a satisfactory explanation of this proclivity of the upper lobes of the lungs to phthisis. The same thing is observed in miliary tuberculosis, in which disease the pulmonary affection is believed to be due to an affection of the tissues at a number of different points through the blood-stream. This fact is opposed to Dr Hamilton's view, expressed in the 'Practitioner' for 1880, that the proclivity of the apices depends upon their being the driest parts of the lungs, so that caseation of catarrhal products is more apt to take place there than elsewhere. He also maintains that there is less expansion of the apices during breathing, and that catarrhal products are consequently more likely to accumulate in them than in other parts of the lungs. Almost exactly the same line of reasoning is adopted by Rindfleisch in 'Ziemssen's Handbuch.' He insists that the upright position of

* It is worthy of notice that, after speaking of the presence of the bacillus in the "Perlsucht" of cattle (cf. p. 315) Koch goes on to say that he detected it in cases in which there were round smooth-walled nodules filled with a cheesy pulp, such as are not generally reckoned to belong to Perlsucht, but to bronchiectasis. It would thus appear that pathologists have too narrowly defined tubercular diseases of the lungs, in animals as well as in man. But my own opinions with regard to phthisis have been based not so much upon microscopical investigations as upon the results of careful study of the appearances seen in the *post-mortem* room of Guy's Hospital during a long period of years. And I cannot help thinking that any unprejudiced observer would inevitably be driven to the same conclusion. Without wishing to detract from the importance of histological inquiries, I am under the impression that the practice of setting aside minute fragments of diseased organs for study at a future time, when the general morbid anatomy of the case has been forgotten, is very apt to lead to one-sided and partial views. What I have found is, that in the same body lesions which would be universally admitted as tubercular are associated inextricably with other lesions, of which the tubercular nature would by many pathologists be denied.—C. H. F., 1883.

the body in man and in the Quadrumana causes the weight of the shoulders and arms to fall upon the upper ribs, and so interferes with their play and leads to a deficiency in the movement of air in the apices as compared with that in the lower lobes. On the other hand, it is certain that the proclivity of the apices is no greater in men than in women, who use those parts of the lungs far more than men do. According to Dr Moxon, the regions which become the earliest seats of tubercle in persons who are confined to bed are the anterior edges; a fact which he explained by supposing that in a bedridden patient these parts are the most, not the least, active in respiration.

The general rule of the proclivity of the apex is liable to some other exceptions. In certain cases the tubercles appear a little lower down, leaving one or two cubic inches at the extreme summit of the upper lobe free, and often the seat of emphysema. Occasionally the middle of the organ is first affected, or even the lower lobe, the upper angle of which is frequently the seat of a vomica in ordinary phthisis. But the tubercular process seems never to spread upwards from the base of a lung into and through the upper lobe. What has sometimes been called "basal phthisis" is a distinct affection, which has been described above under the name of "chronic pneumonia" or cirrhosis of the lung (*supra*, p. 1007).

Phthisis tuberculous.—A common appearance is for the upper lobe to present a dense fibroid mass (perhaps containing more or less numerous cavities), while in the middle of the organ there are cheesy patches and in the lower lobe grey tubercles, scattered or in groups. Or, again, the affection in one lung may appear to be typically fibroid or typically pneumonic throughout; yet in the opposite lung, in which the disease is of more recent origin, there may be clusters of tubercles; and these may themselves be caseating, whatever the character of the change in the lung first affected. Lastly, the pulmonary lesion may appear to be pneumonic, or to be fibroid, not a single tubercle being discoverable, even in a state of caseation; and yet in some distant part of the body there may be tubercular lesions of the most characteristic kind in the ileum, or ulceration at the back of the vocal cords.

The following facts illustrate this point. In 1876 the author examined the body of a girl, aged sixteen, who died of what was regarded as pneumonic phthisis; in one kidney, traversing its cortex from the surface to the medulla, was a single linear tuberculous mass. In 1878, in a case of pneumonic phthisis, in which the affected part of the lung showed only a cheesy infiltration breaking down into sinous cavities without any distinct walls, there were not only small caseating points and ulcers in the intestine, but in the liver several tubercles as typical as possible. In 1876 the lungs of a child, aged six, presented a remarkable example of "fibroid phthisis;" in her intestine there were a large number of ulcers, with most abundant subserous tubercle. In 1879 a typical case of fibroid phthisis of the apices of the lungs showed indurated tubercles lower down; in the kidneys and the prostate of the same patient there were caseating vomicæ. In 1878, in a woman of thirty-three, the disease consisting mainly of grey induration of the pulmonary tissue, there being very little tendency to caseate, both adrenal bodies contained cheesy nodules, and there were yellow tubercles in the liver.

The way in which phthisis begins confirms the belief that it is from the

very outset tuberculous. The following are nine cases of very early phthisis found in persons dead from other causes. In 1881 a man, aged thirty, died of delirium tremens in Guy's Hospital; in the upper parts of both lungs there were miliary tubercles in groups. In the same year a man, aged thirty, died of caries of the spine with psoas abscess; in the apex of each lung there were grey translucent tubercles, some scattered, some in clusters, occupying only a square inch of the cut surface; the other parts of the lungs were quite free. In 1879 a youth of nineteen died of spinal disease, with a scrofulous kidney; in the apex of the right lung there was a single cluster of the most typical firm grey tubercles, none of which showed any tendency to caseate. In the same year a man, aged thirty, died of "sacro-iliac disease," which, although the result of injury, was accompanied with tuberculous affections of the prostate, kidney, spleen, and lymph-glands; the extreme apex of the right lung contained scattered grey miliary tubercles, without the slightest caseation, and with no induration of the surrounding pulmonary tissue. In 1877 a boy, aged ten, was killed by fracture of the spine; he appeared to have been strong and healthy, but in the apex of each lung there were miliary tubercles. These cases were observed by the author; and Dr Moxon's experience at Guy's Hospital was very similar. In 1869 a child, aged two years and three months, died of croup; in the left lung, below the apex, there were found several clusters of grey tubercles, one of them with caseous material in its centre. In 1867 a man, aged twenty-seven, was killed by accident, with fracture of the skull; at both apices, especially the right, there were recent miliary tubercles, in smaller or larger clusters. In the same year a man, aged twenty-two, died of typhus: in the right upper lobe there were many clusters of miliary tubercles, some already softening. In 1868 a woman, aged twenty-one, died after amputation of the thigh for disease of the knee-joint; in each apex there was early phthisis with clustered tubercles, some caseating; there was also a small vomica.

Even when the tuberculous character of an incipient pulmonary lesion might fairly be doubted, one may discover elsewhere morbid changes the nature of which is indisputable. Thus, in 1874, in examining the body of a girl, aged eighteen, who had died after excision of the knee-joint, the author found in the apex of the right lung a mass, the size of a marble, consisting of a cluster of yellow softening granules, which might naturally have been set down to catarrhal pneumonia; but the bronchial glands were caseating, and one of them contained the most typical grey tubercles.

Seat of the tubercles.—If we consider that there is scarcely a structure in the human body which is not liable to the growth of tubercles, we shall surely think it very improbable that in the lung their development should be limited to any one rather than another of the various tissues which make up the organ. Rindfleisch, however, maintained that the morbid process in phthisis begins definitely just where the bronchioles open into the alveoli, the earliest change being a "tuberculous infiltration of all the edges and processes" which exist at these points, and which contain muscular and elastic tissues, as well as fibrous. The occurrence of such a change at the extremities of several adjacent tubes, and its extension along the walls of the tubes themselves, would no doubt account satisfactorily for the "racemose" distribution of pulmonary tubercles on which Carswell used to insist, so that the phrase "Carswell's grapes" was invented to keep it in recollection. But his drawings illustrating this point are diagrammatic and accom-

modated. It is very seldom that one sees anything like a "peribronchial" distribution of clustered tubercles. And Dr Hamilton, in the 'Practitioner' for 1880, describes tubercle in the lung as generally beginning in a little cellular projection on one side of an alveolus, which afterwards becomes somewhat pedunculated and hangs into the alveolar cavity. When these alveoli lie adjacent to one another it may project into all of them at once. At first it pushes before it the epithelium and even the alveolar capillaries. But soon it breaks through and destroys the alveolar wall, so that a uniform rounded mass results, in which the outlines of the original air-vesicles are barely recognisable. The cells of the tubercle may, Dr Hamilton thinks, be derived either from the connective-tissue elements of the alveolar wall, or from the endothelium of certain of its capillaries, or both sources at once. Sometimes a tubercle sprouts from the inner coat of a branch of the pulmonary artery, starting perhaps from the endothelium, but soon involving the rest of the *tunica intima*, and almost occluding the channel of the vessel. Other tubercles lie in the course of the pulmonary lymphatic vessels contained in the periarterial and peribronchial sheaths, the interlobular septa and the deep layer of the pleura.

In some instances of phthisis, tubercles, scattered or in clusters, spread slowly through the lung, with little or no change in the intervening tissue. But, as a rule, this undergoes early consolidation, so that the tubercles come to be embedded in a more or less homogeneous mass. Sometimes, the substance of the lung is involved uniformly from the apex downwards, the edge of the consolidated area having a festooned outline, not unlike that of the border of a malignant new growth. Much more frequently, even when part of the upper lobe is universally affected, there are more or less numerous independent nodules of various shapes and sizes, lower down; and between and below these again, scattered tubercles may generally be seen in abundance. The character of the infiltrating material varies widely in different cases. It may be a soft, semitranslucent, pinkish substance, or a yellow friable tissue, the result of caseation. In other cases it is firm, dark, and tough, constituting one form of Addison's iron-grey induration, or it may have a "marbled" aspect, crossed by bands and seams of well-developed fibrous tissue, and darkened in all degrees of depth, up to perfect blackness. There are comparatively few cases in which caseation may not be found in some part of the lungs; and when the parts earliest affected are fibrous and of an iron-grey colour, those recently involved are often soft and yellow.

Vomicæ.—In all but very exceptional cases of phthisis the process of consolidation is followed more or less quickly by one of *ulceration*, leading to the formation of cavities technically called *vomicæ.** The tubercles no doubt soften in their centres, as they do elsewhere, and there is no reason why a vomica should not result from the breaking down of caseous material derived from tubercles alone; but, as a matter of fact, the formation of cavities involves the destruction of infiltrated lung-substance as well.†

* *Vomica*, a foul sore, an internal abscess: an old Latin word ('Liv. Hist.,' xxv, 72), applied by Celsus (lib. iv, cap. 8) to abscess of the liver as well as of the lung.

"Et phthisis et vomicæ putres."—Juv., xiii, 95.

† Sir Robert Carswell used to declare that sections of bronchial tubes with pus in their interior were frequently mistaken for softening tubercles. In this I feel confident he was wrong. In two or three exceptional instances I have thought, on first glancing at the cut surface of a lung, that I saw tubercles, when there were really only the open mouths of swollen tubes; but an instant afterwards I have perceived my error, because the slightest pressure below has made pus well up from them in large quantities.—C. H. F.

One characteristic appearance, which may be observed in various other organs besides the lungs, is the presence of a caseous zone of definite thickness between a vomica and the surrounding normal tissue. Such a zone is generally an indication that the disease is still spreading, and it is the chief means by which vomicæ increase in size. As they enlarge, cavities originally distinct are very apt to open into one another, and thus a single cavern of irregular form may be produced. Sometimes the destructive process remains limited by the lobar septum; sometimes this becomes ulcerated through, so that both the whole of the upper and a large part of the lower lobe may form one huge sac.

Sooner or later, if the patient should survive long enough, the further extension of a vomica becomes arrested. The indication of this change is that the interior of the cavity ceases to be rough and shaggy with adherent cheesy débris. A fibrous wall becomes developed, and its inner surface gradually assumes a smooth, polished appearance, exactly like that of a mucous membrane.

Such smooth-walled vomicæ are often crossed by fibrous bands or *trabeculæ*. Each consists of a mass of condensed pulmonary substance, with fibrous tissue that perhaps originally belonged to interlobular septa. In all probability some trabeculæ are remains of partitions that at one time separated vomicæ which have since coalesced. Others contain obliterated branches of the pulmonary artery; and sometimes several can be seen to spread away from a point situated on that side of the cavity which is nearest the root of the lung, so that their formation has obviously been the result of the resistance offered by the arterial walls to the process of ulceration. Ultimately the trabeculæ themselves give way, and their loose ends may then be seen hanging into the interior of the vomicæ. In very large cavities a bundle of such ruptured trabeculæ may sometimes be seen, the relation of which to the pulmonary artery is at once shown if a probe is passed into that vessel from the heart. Sometimes a pervious channel persists for some little distance in a trabecula, a fact which we shall see to be of clinical importance.

According to many observers of authority, certain smooth-walled cavities have an entirely different origin from that just assigned to them, being dilatations of bronchial tubes, instead of being formed by ulceration (cf. p. 973). Tubes do, indeed, almost invariably open into them more or less freely, the branches of the bronchial tree possessing no such power of resisting ulceration as belongs to the arteries. The idea of regarding the cavities in question as "bronchiectases" seems to have originated with Laennec. In all probability what first suggested it was the difficulty of understanding how a vomica formed by ulceration could acquire anything like a mucous membrane. But this goes for very little now that we know how readily such a structure can be pushed forwards over a raw surface from an edge of skin or of mucous membrane, as, for example, in the case of a rectal fistula. As a matter of fact, moreover, it is doubtful whether smooth-walled pulmonary cavities ever have a continuous epithelial lining. Dr Ewart, in his Gulstonian Lectures for 1882, says that this is wanting, except where there are "scattered islets of mucous membrane," the remains of "outlying bronchi intersected by the cavity wall."

Dr Hamilton, in the 'Practitioner' for 1879, declares that cavities, which cannot be dilated bronchial tubes, often have an epithelium "most typically columnar and ciliated;" and he explains the occurrence of bronchiectasis, and the sinuous and irregular outlines of the cavities which he

believes to be of such a nature, by referring it to the traction of bands of fibrous tissue radiating away from the sides of the cavity at different points. What seems to prove that the cavities in question are really vomicæ is that the earlier stage of the process of dilatation is never seen. If the view adopted by Dr Hamilton were correct, one ought, towards the margin of the affected part of the lung, to see tubes which could still be traced on to their extremities, but the sides of which were beginning to bulge out here and there. On the other hand, what one does commonly find are all possible transitional varieties between smooth-walled cavities and unmistakable vomicæ. The former are seen towards the apex, where the mischief is of oldest date; the latter lower down, where it is of more recent origin. Moreover, smooth-walled cavities often riddle the substance of a diseased lung in all directions, communicating freely with one another on every side, so that an ulcerative process must clearly have been concerned in their formation.

The contents of vomicæ vary widely in kind and in amount. When they are recent they often show masses of cheesy débris. Such masses, even if they are at first too large to pass out through a bronchial tube, probably crumble into fragments in the course of time, and are expectorated. Cavities of old date usually have pus in their interior. This of course implies that there is no very free communication with the bronchial tubes, and the fact is that in old vomicæ there is a tendency for the orifices of the tubes to contract until they become very narrow. One often finds that a tube of considerable size, into which a large catheter might be passed, has an opening into a cavity that will but just admit a probe. When such is the case, a turgid condition of its lining membrane may easily block it altogether.

It is remarkable how seldom the contents of phthisical cavities putrefy; they often have a faint, sickly odour, but they very rarely become fœtid, nor do they often undergo that peculiar acid fermentation which is so apt to arise in cases of chronic bronchitis with dilatation of the tubes (p. 975). When there is free escape of pus from vomicæ, their lining membrane may continually pour it out with large daily expectoration. But sometimes the walls are found at an autopsy perfectly dry, and the interior empty; in such cases there may be no expectoration whatever during life. In 1854 Dr Bristowe showed to the Pathological Society a specimen of such a quiescent cavity having adherent to its inner surface a soft, greenish, powdery mass of fungus, consisting of a branching mycelium, and of spores arranged upon rounded heads with thick stalks (*Aspergillus fumigatus*).

Adhesions.—A constant attendant upon phthisis is a local pleurisy, which leads to a gradual closure of the upper part of the serous space on the affected side. As a rule, these pleuritic adhesions are non-tubercular, and Rindfleisch insists on the extreme vascularity of the "false membranes" which unite the two surfaces, as contrasting with the deficiency of vessels in the substance of a fibroid lung. Not infrequently the adhesions are so thick and dense that it is impossible to remove the lung without free use of the knife.

Involution.—To complete the morbid anatomy of phthisis we have still to discuss the processes by which tuberculous lesions in the lungs become obsolete, so that they cease to threaten the patient's life, or even to impair his health; for tubercular inflammation is not an incurable process.

Relics of former mischief are frequently discovered in the lungs of persons who have died at various periods of life and of every kind of disease

or injury. In May, 1880, Dr Heitler, of Vienna, brought before the Medical Society of that city an analysis of all the cases of this kind that had been met with in a series of 16,562 autopsies between the years 1867 and 1879. Excluding all cases in which death was due to phthisis (among which there must of course have been many other instances of a previous attack of the same affection), he found that there were no fewer than 780 (or almost exactly 5 per cent.) in which obsolete tuberculous masses were present. Of the patients 503 were males, 277 females. The number of those who died of tuberculous affections of other organs was 101. A point of great interest is that the proportion of cases at different ages went on regularly increasing for each decennial period up to sixty years of age. Among persons aged from ten to twenty there were 12; from twenty to thirty, 105; from thirty to forty, 131; from forty to fifty, 156; from fifty to sixty, 157; from sixty to seventy, 36; from seventy to eighty, 153. It is true that no positive conclusion can be drawn from this fact, in the absence of information as to the proportion of persons at different ages in the total number of autopsies, but it is difficult to escape the inference that the time at which the pulmonary lesions were originally developed must, in a considerable number of instances, have been during adult life. In no fewer than 651 cases both lungs showed signs of past disease, though generally to an unequal extent; in sixty-eight the right lung was alone affected, in sixty-one the left.

There is a definite history of a former pulmonary affection in a case cited by Rindfleisch in 'Ziemssen's Handbuch.' It occurred in a man over fifty years of age, who died of enteric fever, fourteen years after having been treated in the same hospital for serious disease of the lung, attended with hæmoptysis and infiltration of the right upper lobe. He completely recovered, resumed his former occupation, and remained well until he took the fever a week before his death. The part of the lung that had been diseased was found to be indurated and shrunken, with surrounding emphysema and dilatation of bronchial tubes.

That such relics of long-passed pulmonary mischief belong to the same affection which, when it goes on and destroys life, is called phthisis, cannot be doubted. For their seat is in or near the apex of the lung, the affected part is more or less indurated, and it is often puckered on the surface or adherent to the chest-wall. On section it presents fibrous bands, or tough masses of fibrous tissue, parts of which are generally deeply pigmented, and in which there are often embedded cheesy or calcareous nodules. Kurlow has found by experiment that such obsolete tubercle is sometimes still infectious when injected, and reproduces tubercle in animals. The cheesy nodules may look very like gummata; they are enclosed in fibrous capsules; not infrequently they are gritty from the deposition of lime-salts in them, or this process may have gone on until they have become converted into hard, smooth calculi made up almost entirely of mineral constituents. In many instances one also observes grey or black indurated tubercles, long obsolete, and probably as old as the cheesy masses. When the fibrous bands have given rise to much puckering of the pulmonary tissue they often look very like cicatrices, and it has been thought that they represent former vomicæ which have undergone obliteration. Although there is no proof of this, there is no doubt that the walls of a cavity may shrink, so that in time it becomes reduced in size. Dr Theodore Williams has shown that this process of contraction of a vomica is often attended by shifting of its position. Unless its anterior surface is closely in contact with a firmly

adherent pleura, the more fixed part of its wall is that which contains the openings of bronchial tubes; consequently it often shrinks away from the front of the lung towards the root. Dr Ewart, in his 'Gulstonian Lectures' for 1882, gives diagrams showing that the pulmonary pleura, if not too extensively fixed by adhesions, may be drawn inwards over such a receding cavity until it forms a deep chink or fissure. The space created by the shrinking of a vomica may be filled up by the adjacent pulmonary tissue becoming emphysematous, the bullæ having been probably formed during inspiration, after the manner suggested by Dr Gairdner (p. 964). More frequently, however, the lower part of the upper lobe of the lung, or (in the case of the right lung) the fore-part of the middle lobe, is uniformly enlarged; if there is a considerable amount of contraction of one, the upper lobe of the opposite one may increase in size until it passes across the median line. Other organs at the same time undergo displacement. The liver or the stomach is dragged upwards, according as the right or the left lung is the one which is diseased; and the heart may be pulled over either to the right, or beyond its natural position to the left. Lastly, the upper ribs are drawn inwards, so that the chest-wall, especially below the clavicle, appears flattened or even hollowed.

Summary.—We may conclude our account of the anatomy of phthisis by saying that one of its characteristic marks is its multiformity. In every case there is more or less evidence of bronchitis, in every case more or less pleurisy, in every case discrete tubercles, grey or yellow, and infiltrating caseous tubercle. In every case there is cartarhal inflammation ("pneumonia"), with softening and destructive ulceration, causing more or less developed vomicæ; and in almost every case there is some attempt at repair, shown by fibrous induration, contraction, and cicatrisation.

On the other hand, pleuritic effusion is rare except occasionally in the earliest stage, and empyema is still rarer. True lobar fibrinous pneumonia is an infrequent and apparently an accidental complication; and neither abscess nor gangrene is met with. Pneumothorax sometimes occurs, and must always be remembered as a possible event. Emphysema, chiefly of the anterior edge of the lungs, is present in almost all chronic cases.

The anatomical lesions which most frequently accompany pulmonary phthisis are ulceration of the *ileum* and of the *larynx*. The latter has been already described (p. 894); the former will be noticed among the diseases of the intestines. Next in frequency comes tubercular pleurisy, then peritonitis, tubercular meningitis and tuberculosis of the spleen, liver, and kidneys, of the testes in men, and the Fallopian tubes in women.

Symptoms.—The clinical recognition of phthisis, as of pulmonary diseases in general, is based partly upon symptoms, partly upon physical signs. But there is no other disease in which diagnosis depends so completely upon the concurrence of the two kinds of evidence. Symptoms alone, when no signs can be detected, may justify a strong suspicion that phthisis is present; but, unless it is confirmed by their subsequent appearance, this suspicion never reaches certainty. On the other hand, when one discovers physical signs of the disease in a person whose health appears perfect—as sometimes happens, for example, in a candidate for life insurance—the inference is, that they depend upon a lesion which, although it was phthisical, yet is now obsolete, at least for the time. Probably physical signs never develop themselves in phthisis without symptoms having preceded them, although the patient

may fail to notice or may wilfully conceal them. A description of the symptoms of the disease will therefore best precede that of the signs.

The symptoms of phthisis fall into two groups. One group includes those which point directly to the lungs; the other those which concern other organs, or belong to the whole body. We will take the latter first.

Emaciation.—Of the general symptoms, one of the most important is progressive loss of flesh. This often occurs with extreme rapidity. Rühle mentions the case of a very bulky woman, who had weighed 240 lbs., and who lost 40 lbs. in the four weeks before she came under his care for hæmoptysis, at which time no physical signs of mischief in the lungs could be detected. Ultimately phthisical patients often lose a quarter or even a third of their weight. The explanation of the wasting is not always obvious. There is often great loss of appetite, and especially distaste for fat in every form, while in some cases vomiting is added to anorexia. But many patients who eat well and appear to digest what they eat, still lose flesh steadily. Nor does the wasting correspond to the degree of pyrexia or to the amount of sweating. There is no question that diminished appetite and imperfect assimilation of food, hectic fever and continued colliquative diarrhœa, profuse purulent expectoration and excessive sweating, each tend to produce loss of flesh; but it almost seems as if the growth of tubercle, like that of cancer, has a certain wasting effect, independently of diminution of the income or increase of the expenditure of the organism. Atrophy probably affects all the tissues more or less; but the heart becomes much less reduced in size in phthisis than in other wasting diseases, as, for example, cancer, probably because the right ventricle has increased work thrown upon it by the obstruction in the lungs.

With the emaciation there is often failure of strength and energy. The patient is no longer able to walk far without fatigue. The duties of the day tire him, so that he is glad to get home and to lie on the sofa until he goes to bed; and in the morning he gets up feeling weary and unfit for the day's work. But in many cases the mental activity and the muscular strength persist to a surprising degree, even in the advanced stages of the disease.

The *skin* is usually moist, sometimes greasy to the touch, but occasionally harsh and dry, with diminished sebaceous secretion—the state known as *xerodermia* or *pityriasis tabescentium.*

The growth of the *hair* is also changed. The straight lanky whiskers and beard of consumptive patients, and the long thin hair upon the chest, often suggest the nature of their disease.

Anæmia is often an early symptom of phthisis. The face becomes pale, the hands are white and transparent. In women scantiness or suppression of the catamenia may be one of the first indications that the health is failing. Œdema of the ankles often occurs as the disease advances, but it is seldom considerable unless there be venous thrombosis. It depends rather on anæmia than upon pulmonary obstruction; and there is never general dropsy or albuminuria, as in cases of chronic bronchitis.

Pyrexia.—When one is consulted by a person who has thus become thin and weak, the first thing to do is to ascertain whether the temperature is raised, particularly in the evening. One should notice whether the palms of the hands are hot, whether the cheeks are flushed and the pulse quickened, and whether there is unusual perspiration at night. The pyrexia of phthisis is altogether atypical, and in different cases it

varies widely in character and degree. It is scarcely ever altogether absent.*

In the most acute cases, which in Germany are called "phthisis florida," the pyrexia may be continuous throughout the twenty-four hours; the temperature may reach 104°, and never fall below 102°, unless profuse sweating should occur, when it usually falls one or two degrees Fahr. It is remarkable that, even when there is high fever, delirium and other cerebral symptoms are often absent; and it is quite an exception for the patient to pass into a "typhoid" condition, with stupor, sordes on the lips, and a dry, brown tongue. Moreover, phthisical patients often retain a much better appetite than would be present in other diseases with a like degree of pyrexia; nor is there generally much complaint of thirst.

Scarcely less acute is the course of other cases in which the daily range of the thermometer is very wide, the maximum perhaps reaching 103° or 104°, while the minimum may be 98·4°, or even lower still. Rühle says that the occurrence of a subnormal temperature, alternating with a high temperature at different periods of the day, is more unfavourable than when the fall is nearly to the normal point. Sometimes the patient experiences a slight rigor or a sensation of chilliness, and then passes through hot and sweating stages, very like those of a paroxysm of ague; and for this phthisis has actually been mistaken by a careless observer.

In other less severe cases the range of the temperature is comparatively slight; the thermometer may indicate 100° or 101° towards evening, but during the rest of the day it is perhaps scarcely, if at all, above the normal point. In the same patient there may be all possible variations in the thermometric readings. Even when pyrexia is generally present it sometimes happens that none can be detected during intervals of days or weeks. Of the cause of the differences in degree of pyrexia in different cases of phthisis no satisfactory account has yet been given. Dr Wilson Fox ('Med.-Chir. Transactions,' vol. lvi) thinks that it is generally proportioned to the extent of the intercurrent inflammation; but he admits that there are many exceptions. Lebert concluded, from an elaborate series of investigations, that the temperature is more influenced by individual idiosyncrasy than by anything else. This, of course, is no explanation at all.

Sweating comes on most during sleep, and some patients cannot doze for half an hour during the day without their clothes becoming saturated. A paroxysm of cough is sometimes the starting-point of such fits of perspiration.

Pulse.—The heart's action is nearly always accelerated in phthisis, and its rate is almost as valuable an indication of the activity of the disease as the temperature itself. Like the pyrexia, it is highest in the evening. It is apt to be much affected by slight exertion, and even by a change of position from sitting to standing. The frequent pulse is generally soft and feeble in quality. Sometimes its rapidity is out of proportion to the degree of fever, perhaps due to the nervous sensibility which forms so striking a feature of many cases of phthisis.

Vomiting is sometimes a conspicuous and early symptom of phthisis, and instances are known of grave error being committed in supposing that the

* Dr Theodore Williams, however, in vol. lviii of the 'Med.-Chir. Transactions,' says that in several of his cases in which active disease was going on in one or both lungs, no rise of temperature took place. And he gives details of an instance in which, although five observations were made every day for a week, the thermometer was never found above 99°.

patient's complaints were all due to disorder of the stomach. The suggestion was many years ago made by Mr Hilton that severe vomiting in phthisis may be due to irritation of the trunk of the pneumogastric nerve by tuberculous bronchial glands. In other cases this symptom is the direct result of a violent fit of coughing.

Diarrhœa is another symptom which often attracts attention in phthisis. It is often due to the presence of tubercular ulcers of the small intestine, or rather, perhaps, to a catarrhal state of the mucous membrane which precedes and accompanies such ulcers. Sometimes diarrhœa from this cause persists for many weeks before any physical signs of pulmonary disease can be detected. In advanced cases another cause of diarrhœa is the development of lardaceous disease in the intestinal mucous membrane.

A minor point, on which French writers have insisted, is the presence of a pink line on the gums close to the teeth. Whether it is seen more often in persons who are consumptive than in others is doubtful.

Aspect.—A phthisical patient often betrays the nature of his disease to the experienced physician at the first glance. Apart from the question (to be considered presently) of there being a special configuration indicative of a phthisical tendency, a bright eye, and a flushed cheek, associated with a pale face, wasted frame, slender fingers, and lank hair, at once suggest consumption.

It is a well-known peculiarity of consumptive patients that they generally remain hopeful throughout their illness, and, though they often suffer much, are as a rule cheerful and uncomplaining. This is in contrast with those who suffer from disease of the heart, but still more with patients who have chronic affections of the abdomen and particularly of the rectum.

Dyspnœa is a much less marked symptom in phthisis than might perhaps have been expected. The gradual onset of the disease and the loss of muscular power and of body-weight keeping pace with the destruction of pulmonary tissue, probably accounts for the fact that a patient, even with advanced phthisis, is often able to breathe quietly, and to carry on conversation with comfort, so long as he is sitting still. As Sir Thomas Watson observes, persons who fear, but will not believe, that they are consumptive, will fetch a deep breath, and bid us remark how thoroughly they can distend their lungs. But any effort or exertion is almost always attended with obvious hurry of breathing in patients who have passed beyond the earliest stage of the disease; and towards the last, orthopnœa is sometimes present in the most extreme degree, so that the patient gasps for breath, while his face and hands are livid and bathed in sweat.

It is no doubt as a consequence of obstruction to the pulmonary circulation that in the more chronic cases of phthisis we see clubbed finger-ends with incurved nails (*ungues adunci*). This affects the toes also, as it does in cases of chronic bronchitis, and of heart disease.

Pain is not commonly distressing or troublesome in cases of phthisis. There may be pain in the shoulder, or beneath the collar-bone, or lower down. But in many cases even this seems to be muscular rather than deeply seated. The pleurisy which invariably fixes the lung to the surrounding structures as the disease advances must be painless, for it is a constant complication. But pleurisy lower down, where there is more movement of the parietal upon the pulmonary layer, is less frequent, and is not uncommonly attended with sharp and piercing pain.

Cough and sputum.—In certain cases a *cough* is the earliest indication

of phthisis. At first it may be very slight, hardly more than a clearing of the throat; or it may occur only in the early morning, or after exertion during the day. It sometimes disappears for a time, to return later on. But ultimately it becomes more and more frequent, until it may cause great distress. It is when cough has been the first symptom noticed, that the disease is said to have arisen out of a "neglected cold."

A dry cough (*tussis sicca*, βῆξ κενή) is supposed to be characteristic of phthisis, hence the phrase "a dry phthisicky cough." After a time, however, there is more or less *expectoration* of a frothy fluid, watery or slightly viscid. The sputa may consist of a glairy greyish material, in which the microscope shows large round granular cells. As the local process advances, the expectoration becomes muco-purulent and occasionally streaked with blood; and it may ultimately be almost pure pus, or pus so intimately mixed with blood that it has a uniform brick-dust colour. In other cases the expectoration consists of round or disc-like pellets that remain distinct from one another in the mucus; they are called "nummular sputa," from their resemblance in size and shape to coins. If received into water they are seen to have a loose flocculent surface, as if they were portions of wool, or as if they had been "nibbled at," to use an expression of German writers. They consist of inspissated mucus or muco-pus, and contain no air, so that they fall rapidly to the bottom, unless they are held up by stringy mucus. They are probably formed in a vomica of some size, not in a narrow tube through which air was constantly passing backwards and forwards, and have become inspissated by absorption of their liquid constituents, until dislodged by a more than usually violent cough. Accordingly, the general opinion that nummular sputa are distinctive of phthisis is not without reason. But it must be remembered that the necessary conditions for their production are afforded by dilated bronchial tubes, as well as by pulmonary vomicæ. This is probably the explanation of a case mentioned by Sir Thomas Watson, in which he wrongly diagnosed phthisis when chronic bronchitis was the patient's disease.

Under the microscope, beside pus-corpuscles and epithelial cells, red blood-discs, elastic fibres and bacilli are the characteristic elements of the sputa in phthisis.

It has long been known that *fragments of pulmonary tissue* sometimes occur, in which the shape of the alveoli is still plainly visible. Dr Fenwick, in the 'Med.-Chir. Trans.' for 1866, showed that their detection is much facilitated by boiling the sputum with an equal part of a solution of caustic soda (gr. xv to ℥j). This dissolves the mucus in three or four minutes. The resulting liquid is then poured into a conical glass which is filled up with water, and the deposit which forms is carefully examined in a shallow cell. Dr Fenwick in one case found 800 fragments in the expectoration of twelve hours. He did not discover them in any case which was at so early a stage that there were no physical signs, but he often succeeded when no signs had yet pointed to ulceration or softening of the lung. The method is of great value in cases in which phthisis supervenes upon chronic bronchitis and emphysema, when the physical signs are apt to be ambiguous. At an advanced stage, when cavities are present, *elastic fibres* may always be found in the expectoration, even though the disease appears to be quiescent.

The detection of the *bacillus* of tubercle (cf. p. 312) in the sputum has now become an important means of diagnosing phthisis. There are many

methods of staining these organisms.* The following procedure devised by Neelsen has been found the most convenient in our wards. A minute quantity of the most purulent portion of the sputum is spread in a very thin layer upon the centre of a glass slide and thoroughly dried over a spirit lamp without charring. The slide is then immersed for five minutes in a beaker containing some carbolic fuchsine solution† which has been previously warmed to about 100° F., or till it begins to steam. The slide is next washed alternately in two beakers, one containing dilute sulphuric acid (20 p. c.) and the other tap water, until the colour, which speedily disappears from the preparation when dipped in the acid, does not return when it is placed in the water. By this means the fuchsine is washed from all parts of the sputum except from the bacilli of tubercle, which hold the stain with great tenacity. To produce a contrast-stain the slide is now immersed for two or three minutes in a concentrated alcoholic solution of methylene blue, washed rapidly in methylated spirit, and thoroughly dried over a lamp. The process is completed by placing a drop of Canada balsam on the sputum and covering with a thin cover-slip. The tubercle bacilli, stained red, are now easily seen in the blue field under a sixth objective, with a bright light concentrated by means of a substage condenser.

Hæmoptysis.—This important symptom is present whenever mucous or purulent sputa contain streaks of blood, or are uniformly discoloured by it as with the rusty sputum of lobar pneumonia. But in practice it is necessary to distinguish from these conditions the expectoration of pure blood liquid or frothy with air. In a large number of cases this occurrence is the first thing which suggests that there is anything wrong with a patient's lung, or indeed that he is otherwise than perfectly well. He perhaps feels a little tickling in the throat, and finds that his mouth contains a fluid which has a salt taste. He looks at his handkerchief, and is horrified to see that it is stained with blood. In some cases he brings up a large quantity at once and for the first time, but this is not the rule. Almost always hæmorrhage continues more or less for some hours, often recurring with each bout of coughing, and very often if unchecked by treatment will go on with more or less interval for several days.

From the days of Hippocrates it has been thought that the hæmoptysis is in such cases the *cause* of the consumption which ultimately develops itself; and two centuries ago Dr Richard Morton included a *phthisis ab hæmoptoë* among his species of that disease.‡ Recently the same doctrine has been revived by Niemeyer. But there is no sufficient evidence that

* See Dr Heneage Gibbes's paper in the 'Lancet' of August 5th, 1883; and Dr Klein's account of Koch's original method, with those of Ehrlich and Weigert, in his 'Micro-organisms and Diseases,' 3rd ed., p. 163; also a full account by Dr Crookshank in his 'Bacteriology' (1886), pp. 162—167. Like all aniline dyes, the colour is apt to fade, but if the slides are thoroughly washed and treated with nitric acid this may be overcome. Specimens still show perfectly well which were made seven or eight years ago.

† Fuchsine, 1 gramme; absolute alcohol, 10 c.c.; carbolic acid, 5 grammes; water, 100 c.c.

‡ "Hoc tamen perpetuo fere observare licet: quoties scilicet hæmoptoë præcedit, phthisin pulmonarem subsequi solere."—'Phthisiologia,' lib. iii, cap. v. He gives three illustrations.

Herodotus relates the following history of *phthisis ex hæmoptoë*, and it is probably the earliest on record. One of the generals of cavalry in the great host with which Xerxes invaded Europe B.C. 480, was Pharnuches, but he never crossed the Hellespont. For as the army was defiling out of Sardis a dog chanced to run under his horse's feet, and the horse, being frightened, reared and threw Pharnuches. After his fall he brought up blood, and the sickness ended in consumption (πεσὼν δὲ αἷμα ἤμεε καὶ ἐς φθίσιν περιῆλθε ἡ νοῦσος), lib. vii, cap. 88.

the extravasation of blood into a healthy lung is ever the starting-point of disease spreading through its substance and destroying it. Under various other conditions—as, for example, after injuries to the chest, and in chronic heart disease—we have frequent opportunities of observing the effects of pulmonary hæmorrhage and hæmoptysis; and few pathologists will assert that they have ever seen it give rise to phthisis. Nor does anatomical experience lead to the belief that blood extravasated into the air-passages is capable of being inhaled into the pulmonary tissue, and there forming solid nodules, as was maintained by Dr Reginald Thompson in the 'Med.-Chir. Transactions' for 1878. According to him they are most often found in three situations—in the upper lobe, in the axillary region, and towards the base, but not posteriorly,—which, he says, are notably those where inspiration produces the greatest expansion of the lungs. Cases are often met with in which inhalation of blood into the lung has obviously taken place; and what is observed is mottling of the cut surface of the organ with red or purple spots, impalpable, devoid of induration, and offering not the slightest resistance to the finger when passed over them. The formation of blocks or nodules of pulmonary apoplexy is a different process, and occurs only when a vessel is obstructed by an embolus. Hence it seems most probable that the congested cheesy bodies to which Dr Thompson refers are really relics, not of hæmorrhages, but of tubercular lesions.

A point mentioned by Niemeyer, to which a certain importance has since been attached, is that in one case, four weeks after an attack of hæmoptysis, he found a bronchial tube filled with adherent softening clot, giving it exactly the appearance of a vein obliterated by thrombus. A similar case has since been recorded by Dr Weber in vol. ii of the Clinical Society's 'Transactions.' In each instance the tube so affected was situated in the lower lobe of the lung. Now, as Traube remarked, such an appearance is so exceptional that very little significance can be attached to it. As a rule, unless a patient has actually been suffocated by hæmoptysis, one does not find any clots in the bronchial tubes after death. Sometimes a clot of considerable size, with branches that had evidently extended into a number of the bronchi, is expectorated a few days after an attack of pulmonary hæmorrhage. There is such a specimen in the museum of Guy's Hospital.

The other evidence brought forward by Niemeyer in support of the existence of *phthisis ab hæmoptoë* was mainly clinical. It consisted partly in the fact that hæmoptysis in patients who subsequently die of consumption often takes place at a time when no signs of mischief in the lungs can be detected on the most careful examination; partly in the fact that the hæmorrhage is frequently followed by fever, acceleration of the pulse, and signs of inflammation of the pulmonary tissue and of the pleura.

The first point is surely worth nothing. We shall presently see that auscultation and percussion frequently fail to reveal lesions which are really present in the lungs, if they happen to be situated deeply or to be scattered widely apart from one another. Take, for example, the case of a patient who is attacked with hæmoptysis, but who recovers from it completely without the subsequent development of any disease, so that the origin of the hæmorrhage remains a mystery. The author once had under his care a lady, about seventy years old, who on two successive occasions brought up several ounces of blood, but who got quite well afterwards, and at no time had any signs of mischief in the lung. The probability is that she really had a small cavity or other relic of former

phthisis, and that this was the seat of the hæmorrhage. Dr Weber has remarked that some of the patients who appear to get a *phthisis ab hæmoptoë* have had a tendency to epistaxis, and asks why blood should not come from the mucous membrane of the bronchi in such persons, as well as from that of the nose. But this appears unlikely.

It often happens that hæmoptysis is directly traceable to some violent effort or strain, such as rowing, running a race, or lifting a heavy cask; but of course that fact is quite compatible with the existence of disease in the lung at the time, and in most cases there is little doubt that early disease was present. Until we get a case of a presumably healthy young man, who has lately spat blood without other signs of phthisis, and has been killed by some accident shortly after, we cannot say that the lungs were in a healthy state. At present we admit hæmoptysis as a first symptom, but not as a first pathological event in the course of phthisis.

Niemeyer's other point was that hæmoptysis is often followed within two or three days by an increase in the temperature of the body and in the frequency of the pulse, and by signs of inflammation of the lung and pleura. Traube remarks, in reference to this, that none of the cases cited by Niemeyer show the absence of pyrexia at the time when the hæmorrhage occurred. But a chart given by Bäumler in vol. ii of the Clinical Society's 'Transactions' does show a rapid rise of temperature from the second morning after the commencement of the bleeding until the sixth day, when it reached 103·8°, and then a gradual fall until the eleventh day, when it became normal. And it must be in the experience of every clinical physician that such a febrile attack of variable duration is of frequent occurrence after an attack of hæmoptysis, and that before it subsides one can often make out distinct signs of consolidation of one apex, which were absent when it began. Still, Niemeyer's interpretation of these facts is not the most probable. It seems far more likely that the hæmoptysis is itself a direct effect of the development of tubercles in the pulmonary tissue. Hæmorrhage is no uncommon symptom of miliary tuberculosis of the lung, and may be immediately fatal at a time when there is neither ulceration nor obvious consolidation of the lung-substance, and when the only lesions found after death are recent miliary tubercles, which had apparently produced no other symptoms whatever. There is no doubt a difficulty in saying how the bleeding is brought about, but it seems very likely that the growth of tubercles in the walls of the alveoli may be attended with an invasion and softening of the coats of many of their capillaries, while at the same time the blood-pressure in them is augmented in consequence of compression of other capillaries. Rindfleisch, in 'Ziemssen's Handbuch,' gives a microscopical drawing, showing the coats of a minute artery actually perforated by a tubercular cell-growth.

In certain cases of phthisis, hæmoptysis is due to a very different cause, namely, to the rupture of the wall of a branch of pulmonary artery crossing the side of a vomica or enclosed in a trabecula. Rasmussen, of Copenhagen, first made known the fact that in many instances of this kind the hæmorrhage is preceded by an aneurysmal bulging of the coats of the vessel. A translation of his paper appeared in the 'Edinburgh Medical Journal' for November and December, 1868, and for August and September, 1869. Since that time the occurrence of such aneurysms in vomicæ has been noticed by many observers. In the 'Pathological Transactions' for 1871 Dr Douglas Powell tabulated a number of cases that had been inspected by him. We have had a specimen in a child under three

years of age. This instance is in itself sufficient to show that the formation of the aneurysm is not the result of atheroma, like that of an ordinary aortic or popliteal aneurysm. Rasmussen was inclined to attribute it to the unsupported state of the walls of the vessel when one side of it is exposed in a vomica. But Dr Powell points out that the coats are much swollen, semigelatinous, and glistening; and it therefore seems clear that their yielding to form a pouch depends on a previous inflammatory change, more or less like that which causes aneurysm in an artery occluded by an embolus. This, indeed, was Rokitansky's account of the lesions which precede large bleedings in phthisis, in opposition to Laennec's theory of diapedesis and Andral's of bronchial oozing. The size of an aneurysm in a vomica is commonly from that of a pea to that of a nut; but Dr Powell speaks of one which was as large as a Maltese orange. The vomica in which it is found is usually an old one with fibrous walls. The point of rupture is a little hole or fissure just large enough to admit a probe. Hæmorrhage may have recurred on several different occasions, at intervals of days or weeks, before the fatal issue. Indeed, death is not by any means always the direct result of an attack of bleeding, and the patient may sink exhausted after having ceased to spit any blood for several days; but in other cases he dies almost instantaneously, with a rush of blood from the mouth and nose; or he may be choked by the blood before it appears externally, so that the hæmorrhage is not suspected until an autopsy is made. On the whole, it is remarkable how rarely even profuse hæmoptysis is the immediate cause of death in phthisis.

Instances are not uncommon in which, without having formed an aneurysm, the branch of pulmonary artery from which fatal hæmorrhage had occurred is found to be perforated by a process of ulceration. At Guy's Hospital the one condition has been as frequent as the other.

Lastly, in some cases, even of advanced phthisis, in which the lungs contain many vomicæ, it is not possible, after the most careful research, to discover what has been the source of the hæmoptysis. No part of either lung may seem to be more deeply stained with blood than all the rest, even though death may have occurred almost immediately.

A point of some importance in regard to cases of ruptured aneurysm, or laceration of a branch of the pulmonary artery, is that the blood which is expectorated by the patient is usually of a bright red colour. For some writers have insisted that this appearance proves it to have been derived either from a bronchial artery or from a pulmonary vein; but it is extremely rare for blood from the lungs to be dark coloured.* In all probability the bright red, arterial appearance, which is usually seen depends not on the blood being derived from a vessel containing arterial blood, but on its having become aërated while it is in the bronchial tubes, where it certainly often is freely exposed to the air, as is shown by the frothy state in which it reaches the mouth. At any rate it is clear that in no case of hæmoptysis can the fact of the blood being bright red be taken as proving that it came from one kind of vessel in the lung rather than another.

* One such case is related by Niemeyer, in his 'Clinical Lectures. The patient had brought up enough blood to fill three basins within a few minutes; it was found to have a thin frothy layer on the surface but below this it was coagulated into a dark, almost black, cake. Anyone might, says Niemeyer, have supposed that it came from a profuse venesection. Probably the appearance depended on the known physiological fact that effused blood gradually becomes reduced below the surface, the oxyhæmoglobin yielding its oxygen to the white corpuscles.

A further point of great interest, on account of its bearing on the question of a *phthisis ab hæmoptoë*, is that in none of Rasmussen's cases of hæmorrhage from aneurysms of the pulmonary artery was any recent pneumonia found at the autopsy, even when the patient had lived for some weeks. If it should be found that no pyrexia develops itself when, in a patient previously free from fever, hæmoptysis results from ruptured aneurysm, or from laceration of a branch of pulmonary artery, it would give the last blow to Niemeyer's theory.

In almost all cases of hæmoptysis, if the bleeding should cease, there is for some little time afterwards a continuance of expectoration of a deeply blood-stained material—clotted blood, or mucus intimately mixed with blood. This is gradually found to alter in appearance, becoming reddish-brown, or brownish-black in colour. Such a change in it should be carefully noted, because it shows that the hæmorrhage is in reality no longer going on; and perhaps this may affect the treatment. But of course there is still reason to fear that fresh oozing may at any time occur.

Concretions.—When the tubercular process in a part of the lung has become quiescent, and calcification of some of the cheesy material has occurred, it not uncommonly happens that the patient ultimately spits up the concretions which are thus formed, and which may be of all sizes up to that of a pea. Sometimes their detachment from the tissues in which they had been embedded is attended with a little hæmorrhage, and Rühle seems to think that there must necessarily be at the time some fresh softening, so that a further advance of the disease may be anticipated. Indeed, that the expectoration of pulmonary concretions is unfavourable was long ago stated by Morgagni. But this occurrence in many cases has not been followed by any serious consequences. In one case it took place at a considerable interval of time after the subsidence of all active symptoms; and the patient in question is living at the present time. It must be remembered, too, that exactly similar concretions may come from the substance of a mediastinal gland having reached the trachea, or one of the bronchi by ulceration. A case in point occurred at Guy's Hospital in 1874; the man, who had been spitting up pieces of calcareous matter every two or three weeks, was admitted into the hospital and died there; and at the autopsy it was found that round the affected gland there was an abscess which had opened into the œsophagus as well as into the right bronchus.

Physical signs.—The examination of the chest in a case of phthisis reveals slow and progressive but usually imperfect consolidation, followed by excavation of the affected parts of the lungs. There are also the signs of concomitant bronchitis and pleurisy.

(1) *Initial stages.*—At the commencement of the disease the signs may be very slight and doubtful, and repeated examinations at intervals of some days or even two or three weeks, may be required, before one ventures to express a positive opinion as to whether mischief is developing or not.

Among the earliest changes to be detected is diminished mobility of the upper part of the chest on one side. Standing behind the patient, with one hand placed lightly below each of his clavicles, the physician can feel that the expansion of the two sides is unequal; one lags slightly behind the other, or one stops in its movements while the other continues to rise.

On percussing with great care, and comparing closely corresponding regions of the chest, he may make out that there is more or less deficiency of

resonance, either in front or behind. A good plan is gently to flick the two clavicles in turn with the finger; the resulting "osteal" sound may then be mixed with unequal degrees of pulmonary resonance on the two sides. It is important to examine the spaces above the clavicles as well as those below them; and by employing different amounts of force in succession one may sometimes find that a particular kind of stroke elicits an impairment of resonance better than others. The suprascapular regions must also be carefully percussed; deep percussion is required to bring out differences of sound here.

On auscultation it may be found that the vesicular murmur is not alike on the two sides. If over one apex it is permanently deficient or even absent there can be no doubt that that is the lung which is affected. In other cases the presence of early phthisis causes the vesicular murmur to be coarser than natural. It is then difficult to determine by auscultation alone which of the two lungs is most likely to be the seat of disease, for an abnormally loud vesicular murmur, instead of indicating a lesion where it is heard, may be compensatory of one on the opposite side. Various modifications in the character of the vesicular murmur may indicate early phthisis. Inspiration may be harsh in quality, expiration may be too distinct and prolonged, or there may be a slight pause between the two.

Again, the inspiratory sound may be interrupted, in accordance with irregularities in the play of the chest walls. These interruptions may be so frequent that the inspiratory murmur has been compared with the sound produced by a revolving cog-wheel (*respiration saccadée*). This must not be taken as necessarily showing that disease is present, for Dr Walshe has "observed it at one or both apices when free from consolidation of any kind." In one of his cases the cog-wheel rhythm was probably due to the action upon the healthy lung of an irritable heart; for the separate sounds which make up cog-wheel breathing may be synchronous with as many cardiac pulsations, as pointed out in the 'Revue mensuelle,' 1877. It seems likely that when a portion of the lung is partially solidified the shock given to it by the beating of the heart, whether directly or through the blood-vessels, may produce a greater effect than on the normal lung-tissue.

One of the signs of tubercular disease of the anterior edge of the lung is an increased loudness of the cardiac sounds in the corresponding subclavian region. In some cases, too, there is heard over the pulmonary artery a systolic murmur. In later stages it may be due to traction by adhesions, or to anæmia, but its early occurrence is not easy to explain.

A somewhat later sign of phthisis is the presence of non-consonating moist sounds at the affected apex. In some cases they are audible only just after the patient has coughed. If limited to the upper lobe, moist sounds are of special diagnostic significance, since a primary bronchial catarrh is probably never thus localised.

(2) *Consolidation.*—No doubt a considerable amount of consolidation may take place in the apex of a lung without any physical signs being audible beyond those which are mentioned in the last paragraph; but as the process of solidification goes further dulness becomes more obvious, and the respiratory murmur acquires the bronchial character. At the same time the voice is transmitted by the stethoscope with increased loudness, constituting bronchophony. These signs are most important; but it is essential to bear in mind what was stated at pp. 934 and 938 of the normal presence of bronchial breathing in certain regions of the chest. Moreover, throughout the right suprascapular, supraclavicular, and subclavicular regions the

voice may in healthy persons be heard more loudly than in the corresponding left regions.

Moist sounds may or may not accompany the bronchial breathing of phthisical consolidation. When present they usually have a consonating character. A very common combination is for the inspiration to be attended with râles, so that no bronchial breathing is noticeable, whereas immediately afterwards a blowing expiratory sound is heard, but no râles.

From an early period of the disease the regions above and below the clavicle on the affected side are commonly found to be flattened or slightly hollowed. This is partly due to wasting of the pectoral muscles, and afterwards to shrinking of the apices.

(3) *Excavation.*—The quality of the bronchial breathing in a case of phthisis may become more pure, more blowing, more tubular, without there being any further change in the affected part of the lung than increasing consolidation; and, conversely, excavation may take place to a considerable extent without the bronchial breathing changing in quality. But one is scarcely ever wrong in diagnosing the presence of a vomica where we hear well-marked amphoric breathing.

It is not infrequent for a phthisical cavity to become so large that the recognition of its physical signs is the key to the diagnosis of the case. One might perhaps have anticipated that the percussion-sound over a large empty cavity would become resonant again, or even tympanitic. It has, however, long been known that this is not so; the thick adherent pleura and the condensed lung-tissue round the wall of a vomica serve effectually to check the vibrations of the thoracic parietes, so that a toneless noise always forms a large part of the sound which is elicited on percussion; but mixed with this are tones of varying quality, due to the vibration of the air within the vomica itself, and thus any of the modifications enumerated at p. 930 may result.

A frequent peculiarity of the percussion-sound over a large vomica is that it resembles the noise produced by striking coins together, or by striking over one's knees the hands loosely clasped. Laennec called such a percussion-sound the *bruit de pot fêlé*, or, in English, "cracked-jar sound" (p. 930). For its production in a perfect form the walls of the cavity itself and the thoracic parietes must be elastic and yielding, the percussion-stroke must be somewhat heavy, and the cavity must communicate freely with the bronchial tubes, and these again with the external air through the open mouth. The reason is that the *bruit de pot fêlé* depends upon the expulsion of air from the cavity, just as in striking the hands over the knee one drives air out through a chink between them.* There are, however, other diseased conditions in which this curious percussion-sound may occur. Thus, according to Dr Gee, it is sometimes obtained over the upper part of the front of the chest in cases of pleuritic effusion, sometimes over islets of unsolidified lung embedded in tissue hepatised in acute pneumonia, sometimes in cases of malignant tumour. In healthy children also it may sometimes occur from a sudden percussion-stroke driving in the yielding parietes of the chest. But, along with other signs of phthisis, it is almost a certain proof of a large empty cavity in the lung.

Precisely similar in its mode of origin to the *bruit de pot fêlé* is a pheno-

* The cracked-pot sound was exquisitely marked in a patient who had, outside the thorax, beneath the pectoral muscles, an abscess-cavity which contained air, and which communicated with a pneumothorax by a narrow hole through the intercostal muscles.—C. H. F.

menon which sometimes attracts the notice of the patient himself as well as of other persons, namely, the transmission of the heart-sounds outwards, so that they can be heard, like the ticking of a watch, at a distance of several feet.* This singular phenomenon would doubtless be much less rare than it is, were it not that a cavity of sufficient size to have a quantity of air driven out of it by each pulsation of the heart very seldom exists, except in the upper lobe.

On auscultation over a large vomica one may obtain any modification of bronchial breathing up to the amphoric. Another modification, which appears to be heard only when a cavity has been formed, has recently received from Seitz the name of *metamorphosing murmur*.† It is probably not very different from what Laennec long ago described somewhat vaguely as the *souffle voilé*. It is said to be characterised at the commencement of inspiration by an unusually harsh sound, which lasts only during one third of the inspiratory period, and gives place during the remaining two thirds to bronchial breathing accompanied by a metallic echo, or to ordinary râles. The moist sounds are often "large" enough to be called gurgling.

All kinds of *metallic phenomena* may present themselves in a very large vomica, exactly as when there is pneumothorax (cf. p. 1048).

Vocal resonance often amounts to pectoriloquy. On the other hand, Dr Walshe insists on the fact that over a large cavity, at least at its upper part, there *may be dead silence*, both respiratory and vocal.

One very rare effect of excavation of the lung is the production of subcutaneous emphysema. A case in point occurred at Guy's Hospital in 1882. The patient had been slowly sinking for weeks, and shortly before his death there was a slight crackling below the clavicle and at the root of the neck. Fräntzel refers to similar instances. As pneumothorax is not present, it must be assumed that ulceration extends through both layers of the pleura, the space between having been previously closed by adhesions.

Involution.—The physical signs of quiescent or retrogressive phthisis vary widely in different cases. Shrinking of the upper part of the chest may go on until the clavicle and shoulder are obviously drawn down. The cyrtometer will show the diseased side to be much smaller than the sound. The percussion-sound is usually very dull; indeed, as Rühle remarks, extreme dulness in phthisis is usually a favourable sign, for it means that dense fibrous cicatricial tissue has taken the place of patches of tubercular pneumonia.

The heart becomes uncovered by retraction of the lung, especially if the left is the one affected. Its impulse may be seen and felt over a much more extensive area than is naturally the case, even as high as the third or the second intercostal space. The stomach also may be drawn upwards to the level of the sixth or the fifth rib. On the other hand, if the right lung is diseased, the heart's apex may be displaced to the right side of the sternum, and the liver may be dragged up as high as the fourth rib.

Extension.—In all cases of phthisis it is important that, while watching the changes that take place in the part first affected, we should also be on the look-out for signs of extension to other parts, or to the opposite lung.

* Many years ago my father showed me a case of this kind which had come under his observation. The sounds were sometimes audible across a good-sized room, but I found that when the patient, a young woman, was made to close her mouth, I could instantly stop them by pressing together her nostrils. Just such a case was brought under the notice of the Clinical Society in 1880, by Dr Frederick Taylor.—C. H. F.

† See von Niemeyer's essay on 'Phthisis' (New Syd. Soc. transl.), p. 54, note.

The frequency of excavation in the apex of the lower lobe makes it advisable to listen carefully on a level with the shoulder-blade, after it has been drawn outwards by the patient crossing his arms.

In advanced cases the question is often not what parts of the lungs are diseased, but what parts remain capable of carrying on respiration. It is surprising to how small an area, at the extreme base of one lung, one may find the presence of a vesicular murmur restricted. Here it will probably be exceedingly loud, an example of compensatory "puerile" breathing.

One must not over-estimate the significance of crepitations and râles when heard over the whole of the back of a lung, for they do not prove that the corresponding lung substance contains more than scattered or clustered tubercles. In cases of acute and general miliary tuberculosis it has often appeared during life that large tracts of the pulmonary tissue were breaking up, and yet after death the pulmonary tissue between the tubercles has been found still crepitant.

But in the majority of cases of phthisis the discrepancy between physical signs and *post-mortem* appearances is in the opposite direction. Clinically disease is perhaps discovered in the upper lobe of one lung; the autopsy shows that nearly the whole of that lung is affected, and also the upper lobe of the other lung. This cannot always be explained by the extension of the mischief in the interval that may have elapsed. We must frankly recognise the fact that the presence of well-marked disease in one apex adds greatly to the difficulty of detecting early mischief in the other apex. The reason obviously is that one has lost the standard of comparison on which one is accustomed to rely.

On the whole, where there are well-marked signs of advanced phthisis in one lung we may be pretty sure that there is early phthisis in the other. It is extremely rare to find vomicæ on one side and no tubercles on the other. This was, however, the case in a young mulatto, who died under the writer's care after an unusually rapid course of pneumonic phthisis. One lung was full of tubercles, the other was only œdematous.

Diagnosis.—The recognition of phthisis, if based as it should be upon symptoms as well as signs, is often very easy. But there are cases in which there is the greatest difficulty in arriving at a right conclusion, and in which, indeed, the only safe course is to reserve one's opinion for a time. The diagnosis between phthisis and other pulmonary affections, particularly chronic pneumonia, has been already referred to (cf. pp. 953, 1010, 1013). In practice the doubtful cases are generally those in which physical signs are either wanting or at least slight and obscure, so that one hesitates as to whether the disease is pulmonary, or whether there is not rather some deeply seated new growth, or some lesion of the internal lymph-glands, or of the thoracic duct, or of the adrenals, by which the patient is wasted and worn down. Often, although the nature of the affection cannot be determined, it is clear that he is stricken by fatal disease of some kind.

But more often the prognosis absolutely depends upon the opinion one may form. The doubt is generally whether the patient, if a man, is suffering from the syphilitic cachexia, or is the victim of hypochondriasis and aggravated dyspepsia; if a woman, whether she is only hysterical. In all cases of this kind the thermometer is of the greatest value. One hysterical affection, which has often been mistaken for phthisis—the "anorexia nervosa" of Sir William Gull—has been already described (p. 822).

In other cases the suspicion of pulmonary disease is based mainly upon the fact that the girl, as is said, "spits blood." A glance at the sputum is sometimes sufficient to remove all uneasiness about this. What is expectorated may be found to be a rather slimy liquid, uniformly tinged of a pink or purple colour, so that it looks like plum juice. It is, in fact, saliva or mucus from the mouth, and the blood comes from the vessels of the mucous membrane. Rühle remarks that this sort of hæmorrhage often occurs in the night, from the patient making sucking movements of the lips and cheeks during sleep; and thus the pillow may show stains of blood, the origin of which seems at first to be inexplicable.

Another variety of sanguineous expectoration is due to the rupture of small vessels at the back of the fauces during violent coughing, or "hawking up" of phlegm. Varicose veins in the pharynx sometimes reveal the source of hæmorrhage.

Hæmoptysis sometimes occurs in elderly persons, not from phthisis or aneurysm, but from degenerated vessels (whether bronchial or pulmonary is not ascertained). This occurred in the writer's knowledge a few years ago, and almost at the same time in two eminent physicians; and it was the subject of a lecture before the Medical Society by Sir Andrew Clark. The condition is clinically allied to that which leads to cerebral hæmorrhage, epistaxis, and hæmaturia; but it is not known whether the vessels are atheromatous or the seat of arterio-capillary degeneration.

We must first make sure that hæmoptysis is really blood from the lungs. Hysterical girls and more responsible persons will sometimes simulate this symptom, and as their own blood is most convenient for the purpose, the microscope will not detect the fraud.

Blood may be spit out mixed with mucus, which has come from the gums, the tongue, the tonsils, or pharynx, or from the larynx and trachea.

True hæmoptysis may occur as a symptom of cardiac disease, of purpura, or any of the severe forms of anæmia; and also as the result not only of fractured ribs and penetrating wounds of the chest, but also of compression of the ribs without their being broken.

Lastly, hæmoptysis, like so many other hæmorrhages, has been supposed by some observers to be frequently *vicarious* of the catamenial function. Sir Thomas Watson, for example, says that this is not at all uncommon, and that it is not usually attended with any peril to life. He cites a case which was observed by Pinel at the Salpêtrière, that home of all that is marvellous in disease, in which a woman was said to have menstruated through her lungs from the age of sixteen to that of fifty-eight, often to the extent of two quarts of blood during a period of two days, while she nevertheless remained plump and healthy. A very different view of this question is taken by Rühle, who will only admit that in patients who already have lung disease suppression of the catamenia (or of a hæmorrhoidal flux) may be followed by vicarious hæmoptysis. He speaks of having seen cases in which this recurred at intervals of from four to six weeks, until a few leeches were applied to the anus with a corresponding regularity. Vicarious hæmoptysis, if it occurs at all, is so rare that we should look with great suspicion on a supposed case of this condition.

Dr Walshe, insisting on the difficulty of diagnosis in early cases of phthisis, advises little weight to be laid on differences in vocal resonance, particularly at the right apex in women, or on harsh or jerking inspiration

at the same spot; and urges the propriety of suspending judgment until a second examination of the chest has been made.

Cases in which in the writer's experience phthisis has been wrongly diagnosed have been apical pneumonia, pulmonary syphilis, and empyema in children. Those in which it has been overlooked have been mistaken for enteric fever of unusually protracted course, bronchitis in elderly people, tubercular meningitis, or idiopathic anæmia.

Cardiac disease in children, gastric ulceration, and chlorosis often simulate phthisis in aspect, but can be distinguished by careful and repeated physical examination.

Course and events.—Phthisis varies greatly in the rapidity of its progress, but its duration is almost always for many months, and sometimes for many years. Trousseau used to say that the only *phthisie galopante* is miliary tuberculosis of the lungs.

The most rapid case of true phthisis on record is probably one related by Traube in the 'Berliner klin. Wochenschrift' for 1867. A man, aged twenty-eight, died, after only thirteen days' illness, of "acute tubercular (caseous) pneumonia." The attack began with rigors and pyrexia; a few days later hæmoptysis set in and continued. At the autopsy all parts of the left lung presented patches of lobular hepatisation, the centres of which were caseating, especially in the upper lobe; a similar affection in an earlier stage existed in the right lung, and both apices showed traces of old lesions. Eight cases have occurred in Guy's Hospital, in each of which there was a definite history that the duration of the patient's illness, from its commencement to its fatal termination, was only from five to twelve weeks. In two instances the attack was attributed definitely to a chill: one man said that he got wet through while working in a potato-field, after which he shivered and became hot, and was never well again; the other, that on a particular occasion he slept with his window open. In almost every one of these cases vomicæ had formed before death, especially in the upper lobes, in the centres of the cheesy masses, which formed the most conspicuous lesions observed at the autopsy.*

The sudden commencement of some of the rapidly fatal cases of phthisis is of great importance in regard to their diagnosis from cases of acute pneumonia of the apex; for the most serious errors of diagnosis have been made between the two diseases. The mode of onset usually affords a means of arriving at a right judgment, but it is evident that this is not always the case; and the only point on which one can fall back seems to be one to which Traube has drawn attention, namely, that in acute phthisis bronchial breathing is not discoverable until much later than in pneumonia of the upper lobe—not until the end of the second week, or even for a longer time still.

If one finds very extensive consolidation in a case of phthisis when it first comes under one's observation, one should always think of the possibility that it may, in part at least, be the result of intercurrent pneumonia, and therefore that the prognosis may be far less grave than it otherwise would have been. For it is a striking fact that when fibrinous pneumonia

* It must, however, be borne in mind that the distinction from miliary tuberculosis may, sometimes at least, be not very apparent. The dissemination of the tubercular bacilli by the blood-current may, if the tubercles to which it gives rise in the lungs are not very numerous, have no apparent effect until they in their turn become starting-points of a local infection, when a disease exactly like ordinary phthisis may arise.

occurs in a person who already has phthisis it often seems to run as favourable a course as if it had arisen in one who was healthy.

But even acute phthisis—"phthisis florida," as German writers term it—may, instead of going straight on to a fatal termination, become arrested, and afterwards run a chronic course. Rühle relates a case in a girl, who seemed to have but a short time to live when she was transferred to his charge from that of Niemeyer, his predecessor at Greifswald. Yet her symptoms subsided, she was discharged from the hospital with signs of a cavity in the left upper lobe, and did not die until the following year, having in the meantime given birth to a child. Pregnancy possibly checked the progress of the disease.

The course of ordinary chronic cases is, almost without exception, interrupted by intervals during which the patient may seem to regain his health. Cough may almost disappear; even the evening temperature becomes normal from day to day, the appetite returns, the face is no longer pale, and the ordinary weight is regained. It is of course true that this favourable change commonly takes place under medical advice, and we shall presently see how important it is that the advice should be well carried out. But sometimes it occurs even in those persons who have gone on working in spite of their illness.*

Duration.—Different observers have made widely different estimates as to the duration of phthisis. Laennec, Andral, Bayle, and Louis each put the "mean duration" at about two years. Dr Austin Flint, in America, found that, excluding acute tuberculosis, the average duration of phthisis was thirty-three months. These estimates apply to the first thirty years of the century. Dr Pollock, analysing 3566 cases observed by him at the Brompton Hospital, found that the "average duration" of these cases while under observation was more than two years and a half, and in the course of that time only 127 ended fatally. What was the real average length of the disease among the whole number of cases he could not tell, but it must clearly have been much longer. It is, however, very difficult to believe that Dr Pollock's cases fairly represent the ordinary course of the disease. There must have been an undue proportion of exceedingly chronic cases, and cases running a rapid course must in some way have been excluded. Still more extraordinary are the statements made in vol. liv of the 'Med.-Chir. Transactions' with regard to the duration of life among 1000 cases of phthisis seen by Dr C. J. B. Williams in private practice between 1842 and 1864. Of the patients in question 198 were known to have died; in them the average duration of the disease was nearly seven years and three quarters. In the remaining 802 patients who were alive when last heard of, its average duration had already been more than eight years. Among these cases, however, none were included which had not been at least one year under observation; and this restriction, besides keeping out of the list

* In January, 1874, a hatter, aged thirty-seven, who said that he had been ailing for six months, came to me with signs of phthisis at both apices. His morning temperature was 101·4°. His father had died of consumption. Notwithstanding my urgent advice to give up work, he did not rest for a single day. The only difference he made was that instead of living away from his workshop in the Borough, so that he was exposed to changes of temperature in going backwards and forwards, he now slept in the same building. For a week or two the physical signs increased, moist sounds becoming audible all over the left lung. But his symptoms quickly improved, and by the end of May he was as stout as ever, and said that he felt nearly well. The signs at the apices, however, still remained. In the following year I heard that he was in good health, with only a little occasional cough. But in 1879 his symptoms returned, and he died in September, 1881.—C. H. F.

all rapidly fatal cases, doubtless weeded it of most who failed to improve for a time under the treatment recommended, and therefore ceased to attend.

That life is sometimes maintained for a great length of time after phthisis has developed itself has long been well known. Sir Thomas Watson alludes to a patient of Dr Gregory's who was at least seventy-two years old when he died, and who from the age of eighteen had never been free from symptoms, "being often hectic, and frequently spitting blood."

The writer has a patient who furnishes almost a parallel history. He comes of a very phthisical family, and developed signs of the disease when under twenty years of age. He then went a voyage to Australia for his health. After repeated hæmoptysis, he recovered enough to marry at the age of twenty-five, and in 1875 came under the writer's care. There were the signs of consolidation of one apex, and of less advanced disease of the other lung. He has again and again spent the winters at Bournemouth, at Algiers, and in Egypt, again and again has had attacks of pyrexia, bronchitis, or hæmoptysis, but he has survived them all, has become stout, and now at fifty is a grandfather, and considers himself out of the physician's hands.

Immediate causes of death.—The fatal termination of phthisis is sometimes sudden and unexpected. In 1866 a gentleman aged twenty-six, who had long been ill, went up to London from Brighton one day to transact some business. At the London Bridge station he was seized with alarming symptoms, and was taken down to Guy's Hospital, where he died within a quarter of an hour from the beginning of the attack. In 1868 a labouring man aged twenty-three, who had been indisposed for some time, was at his usual work in the Borough, when about 2 p.m. he began to suffer from dyspnœa; this rapidly got worse, and he was carried to the hospital and died in two hours. In neither case did the autopsy show why death should have occurred at that particular time.

Pneumothorax often brings more or less immediate danger to life. Nevertheless, when the immediate effects are got over, the consequent collapse of the lung appears to be unfavourable to rapid progress of the disease; so that if the other lung is but slightly affected the patient's condition may, at least for a time, improve. Some practitioners, acting on this hint, have ventured to puncture the pleura and thus produce pneumothorax, with the hope of checking severe hæmorrhage.

An accident, happily rare, that may bring phthisis to a sudden close is pulmonary *embolism*, resulting from thrombosis of the femoral vein.

Syncope is sometimes the cause of death; or it may arise from sudden exhaustion of the respiratory centre. Indeed, it is not very uncommon for consumptive patients to be found unexpectedly dead in bed.

In other instances phthisis ends fatally by the supervention of tubercular disease elsewhere than in the lungs, by *tubercular meningitis* or peritonitis, by tubercular pyelitis, or by solitary tubercle of the brain.

It is a remarkable fact that *hæmoptysis* is very rarely the immediate cause of death in phthisis. Considering that it is present in more than four fifths of consumptive cases, it is exceptional to find a patient "choked in his own blood," although every practitioner has seen that event.

The most serious symptom towards the last may be *diarrhœa* resulting from tuberculous ulceration of the intestine, or the *dysphagia* and the other distressing symptoms produced by a like affection of the larynx.

The following non-tuberculous affections are not infrequently fatal

complications of phthisis: parenchymatous nephritis, typhlitis with peritonitis, and abscess of the brain.

The coincidence of *fistula in ano* with phthisis is one which requires brief mention. Dr Pollock points out that it occurs far more often in males than in females, and most commonly in persons who are no longer young, the most frequent age for it being from thirty-five to forty-five. The disease of the lungs has very generally advanced to the formation of vomicæ before the fistula appears. Many observers, including Dr Pollock, are of opinion that in such cases no operation should be attempted; for, when it is successful, the phthisis is very apt to assume increased activity two or three months later. But there seems to be no evidence that the cure of a fistula in a person not already consumptive renders him more liable than before to the supervention of pulmonary disease. In such cases the fistula is probably not tubercular in origin.

Finally, *lardaceous degeneration* plays a very prominent part in bringing to a close many cases of phthisis. If the intestines be involved, an intractable diarrhœa may result, which cannot be distinguished during life from that of tuberculous ulceration. But it is chiefly by affecting the kidneys that this kind of degeneration acquires its clinical importance. General dropsy sets in, and the patient acquires more or less of the appearance usual with those who are affected with Bright's disease. Indeed, tubal nephritis sometimes comes on in phthisis without there being any lardaceous change discoverable in the renal glomeruli or vessels even with the microscope. It is, therefore, not safe to diagnose a lardaceous affection of the kidneys from the mere fact that the patient has albuminuria. According to observations made by Dr Theodore Williams, recorded in a paper read before the Royal Medical and Chirurgical Society in 1882, the occurrence of albuminuria in phthisis has the effect of masking the other symptoms, and especially of making the range of temperature lower.

Cases of recovery.—Phthisis was until lately regarded as certainly fatal; we now know that this is not the case, partly through recognising by help of the stethoscope its existence and early stages, partly through the knowledge derived from morbid anatomy.

Again and again we find in the deadhouse traces of obsolete phthisis in adhesions, cicatrices, and calcareous deposits which occupy the apices of one or both lungs in the bodies of those who have died of some acute and independent injury or disease (cf. p. 1061). Such persons must have suffered from phthisical symptoms at some time of their lives.

Hospital practice gives too unfavourable an estimate of the prospects of phthisical patients; for the poor seldom apply for either indoor or outdoor relief until the early stages are past and the disease has gained a firm hold on one or both lungs. In private practice we see cases earlier, and the desirable treatment can be better followed out. But here many of the cases which recover come to us in what used to be called the "pretubercular" stage, when we rather forebode than diagnose the fatal disease. They improve under treatment, and we do not see them again.

With all these drawbacks few physicians have not been fortunate enough to see unmistakably phthisical patients improve, recover health, and continue many years without return of their symptoms.

The following are some of the cases of "cured phthisis" which have come under the writer's notice.

A lad of seventeen, tall, pale, and delicate in appearance, with cough and physical signs of catarrh at one apex. Was sent to Algiers, and returned two years later stout and well, with no symptoms and no physical signs of the disease.

The patient above mentioned (p. 1079), in good health after more than thirty years of phthisical symptoms.

A young man about nineteen whose mother died of phthisis, who was of typically phthisical aspect, and who developed catarrh with anæmia and loss of flesh. He was sent into the country to live in the open air for several months, and recovered. He had a "break-down" with suspicious symptoms when about thirty-five, but quickly recovered, and is now free from all phthisical symptoms at the age of fifty-three.

A young theological student was attacked by hæmoptysis and other signs of consumption. He was sent to Montpellier, where he spent more than a year and finally recovered his health. He has lived a most useful and laborious life, and is still preaching at the age of seventy-six.

A young physician of great distinction and greater promise was attacked with pleurisy and other symptoms of unmistakable tubercular character: there had also been several cases of phthisis in the family. He went out to an elevated city in South America, and has continued well and able to practise for now twelve years.

A medical student with decided symptoms of hereditary phthisis, after careful treatment for seven years in this country, settled at a watering-place in the South of Europe, and has pursued his profession there for the last eleven years.

Prognosis.—From what has been stated in the preceding paragraphs it may easily be imagined that to give a correct prognosis in phthisis is no light matter. And in point of fact those physicians who have the largest experience are precisely those who most strictly abstain from attempting to predict the duration of life among their patients.*

We have followed usage in dividing the *anatomical* course of phthisis into three stages: the *first* stage of the "formation," deposition, or growth of tubercles; the *second* of their "softening;" the *third* of their "elimination" by the process of excavation. But, as already pointed out at p. 1074, the moist sounds which are supposed to indicate "softening" are very apt to be fallacious. These so-called stages have reference only to the local process in certain parts of the lungs, and not at all to the disease as a whole; for while vomicæ exist in one or both apices, tubercles are commonly being formed lower down. To speak of these as *clinical stages* of phthisis leads to a misconception of their significance in prognosis. To every patient, as well as to his friends, it cannot but appear to be a matter of course that in a malady like phthisis the third stage must be the worst. And yet it is no paradox to say that the contrary would often be nearer the truth.

A factor which, more than any other, requires to be taken into account in attempting to determine the probable course of the disease is its greater or less tendency to advance rapidly in that particular patient. In different cases the differences in this respect are enormous; and it does not appear that any explanation of them can be given, except that, as a rule, the progress is quickest in those who have a strong inherited tendency to con-

* See on this difficult question the sections on prognosis in the works of Dr Walshe and of Dr Williams, and the monograph of Dr J. E. Pollock.

sumption. The formation of a large cavity takes a long time, especially if its walls are to acquire a smooth lining. Hence, whenever the morbid process spreads with much rapidity through one or both of the lungs, the opportunity for such cavities to develop themselves is wanting. In other words, the fact that a case presents the physical signs of the third stage is proof that its course has been such as generally warrants a comparatively favourable prognosis. As a matter of experience, patients with large vomicæ often go on year after year with but little change in their condition, and even with enjoyment of life. Dr Walshe speaks of two singers—a distinguished contralto and an excellent soprano—as having within his knowledge continued to perform at the Opera "while the excavating process advanced in their lungs."

Again, one is compelled to speak very guardedly of the probable duration of phthisis, if physical signs indicate that the morbid process is still actively going on in any part of the lungs, whatever may be the stage to which it has reached in the apices. One must not forget, too, that although in the lung first affected its progress may have been slow, it may hurry on to a fatal termination when it passes to the other lung.

The degree of severity of the general symptoms is very important in regard to prognosis, especially the rate of the pulse and the height of the temperature. But it must be remembered that other causes may render the pulse rapid as well as activity of local mischief. And the existence of pyrexia, as has been shown by Dr Theodore Williams, is not incompatible with gain of weight—nor even, we may add, with the subsidence of many of the other symptoms of the disease—provided that the patient eats and digests well.

The majority of cases of acute or "pneumonic" phthisis occur in young subjects, whereas "fibroid" phthisis, the most chronic form of the disease, is more frequent in those who are advanced in years. This seems to have led to the idea that the prognosis is more favourable in proportion as the patient is older. Dr Walshe, however, says that his observations at the Brompton Hospital failed to confirm such an opinion; and Lebert (in vol. xi of the 'Deutsches Archiv') observed that age seems to have little influence on the intensity of the pyrexia, which we have seen to be one of the most important factors in determining the rate of progress of the disease. It can hardly be doubted that in this disease, as in almost every other, the patient's power of resistance and his capacity for repair must alike diminish as he grows older.

In women the duration of phthisis is, on the average, shorter than in men. In children the disease is much less common than general tuberculosis; when present it runs a rapid and febrile course.

Hæmoptysis is not in itself a dangerous symptom, and cases of recurrent severe hæmorrhage belong, as a rule, to the chronic forms of the disease.

Hereditary cases are the worst, particularly when the hereditary tendency shows itself early.

On the whole, good appetite and increasing weight are more important as favourable tokens than absence of well-marked physical signs.

Ætiology.—The discovery of a specific bacillus in all tuberculous lesions has greatly disturbed the question of the origin of phthisis. And yet the constant presence of a microbe is far from deciding the whole of ætiology. In the most exclusively and directly contagious diseases,

syphilis, typhus, smallpox, none has as yet been certainly discovered. Erysipelas and cholera, in each of which one is present, are not in the ordinary sense infectious.

We have already considered the evidence that tuberculosis generally is a specific disease, with the constant presence of a definite bacillus, and found that it fulfils the criteria laid down (*supra*, p. 312 and p. 13). We have also in this chapter endeavoured to show that pulmonary phthisis is pathologically one and the same disease—tubercular inflammation of the lungs. It follows that phthisis depends on the presence of Koch's bacillus, and the conclusion is corroborated by its being so constant in the sputa that its presence there has become a valuable means of checking our diagnosis in doubtful cases. Moreover, it has been detected by Dr Vincent Harris in old museum specimens of phthisical lungs ('St Barth. Hosp. Rep.,' vol. xxi).

Admitting, however, the constant presence of the bacillus, we have, as in other specific diseases, to determine the power of resistance of the tissues to its invasion. This varies with different contagia. That of smallpox and of syphilis is so efficient, that once taken into the lymph-channels or the blood it probably produces the disease in every case. But even here what is so certain a poison in man fails with most at least of the lower animals; and the most efficient contagia may fail in protected organisms. Probably most persons are partially protected against the invasion of enteric fever or erysipelas.

It seems likely that the microbes of tubercle are so widely diffused that all dwellers in cities, at least, must again and again be exposed to their action; yet how comparatively few become tuberculous! Hence we must, in addition to the necessary "exciting" cause, the bacillus, recognise "predisposing" causes in whatever weakens the resistance of the organism generally or of the lungs in particular, and so allows of the "efficient" cause of all the symptoms of phthisis—*i. e.* the inflammatory lesions which follow the permanent lodgment and multiplication of the bacillus.

Of these predisposing causes the most effectual is the fact of parents having suffered from the same disease, which we state abstractly as hereditary *disposition*, or, to use the Greek form of the same word, *diathesis*. The others are either general, or consist in local pulmonary lesions.

i. *Direct contagion.*—In discussing the subject of tubercle in general (p. 317) we saw that clinical observation is altogether opposed to the idea that direct *infection from* another patient is at all common in the ætiology of tubercular diseases.

Of the fact that consumption is not communicated as a rule directly from one person to another no better illustration could be given than a statement published in 1867 by Mr Vertue Edwards, who had then for seventeen years been resident medical officer at the Brompton Hospital. In that period he remembered personally fifty-nine resident medical assistants, whose duration of office averaged quite six months. Of these he believed all but two to be alive; one had died of aneurysm, one of some cause unknown; three, still living, were said to be consumptive. Very many nurses had been in residence from periods varying up to eight, twelve, or even twenty-four years. Of the head nurses, who slept each in a ward of fifty patients, only two were known to have died—one of apoplexy; the other, after an unhappy marriage, of phthisis. No under nurse, so far as he was aware, had died of phthisis. The matron and her two predecessors,

as well as the chaplain and his two predecessors, were all alive. Of the physicians, whether for in-patients or out-patients, all were living except two; one had died of causes unconnected with disease of the lungs, the other from some disease of unknown nature, after twelve years' absence from the hospital. Mr Edwards himself happily survives after forty years.

The fact that phthisis does not commonly spread from a patient who remains in his home to brothers, or sisters, or other relatives, is the more striking because they must be supposed to have inherited more or less predisposition to the disease.

In Dr Weber's cases, recorded in the Clinical Society's 'Transactions' for 1874, the disease seemed to pass immediately from husbands to their wives. The husbands, all of whom were affected before marriage with pulmonary tubercle, were nine in number; but the deaths from phthisis among their wives were as many as eighteen: one lost four wives in succession, one lost three, four lost two each, three lost one each. In seven out of the nine husbands there was a decided family taint; the wives were with one exception free from any such taint, and they were all healthy at the time of marriage. The disease ran a very rapid course in all the wives, terminating in several instances within twelve months, and being never prolonged beyond eighteen months. It was not caused by anxiety or fatigue in nursing the husbands, for the husbands were all apparently well, and none of them succumbed to phthisis until long after their wives. Almost all the wives bore children to their husbands, so that it is perhaps possible that infection took place through the fœtus; but about the state of health of the children nothing is said.*

Judging by the analogy of syphilis, we should say that either infection took place through the ovum or else by direct transference of contagion from local tubercular lesions of the epididymis, but there was no evidence of either; and it seems more probable that the infection was by the breath independently of sexual intercourse.

Dr Weber was acquainted with only thirty other consumptive husbands whose wives escaped phthisis. But in all likelihood this was an accidentally small number; and among twenty-nine consumptive wives who married healthy husbands, only one lost a husband from phthisis.†

The possible infection of phthisis is no new doctrine. Morton wrote in 1697, "I have often found by experience that an infected person may poison a bedfellow by a kind of miasm like that of a malignant fever." In

* Dr Weber seems to have been disposed to think that the seminal fluid was the medium of transference of the disease. But even if this were the case, it does not follow that there must have been conveyance of a specific contagion. May not such cases merely afford another instance of that inexplicable influence of impregnation which stamps on the female organism the characters of the male, so that they can be transmitted long afterwards to offspring by a different male? Cases of this kind among the lower animals are well known to be frequent; and it is said that similar cases occur as the result of sexual intercourse between human beings belonging to different races. The following case, if not merely accidental, was probably an instance. A candidate for life insurance, whose mother had had two husbands, said that the first husband and several of his children had died of phthisis; the second husband was free from all tubercular tendency, but the eldest of the offspring of this marriage nevertheless became affected with the disease.—C. H. F.

† On this subject see the facts recorded in the 'Collective Investigation Record,' "Report on the Communicability of Phthisis;" and also a paper by Dr Burney Yeo, in which he skilfully states the case for regarding phthisis as a contagious disease ('Brit. Med. Journ.,' April 18th, 1885). Dr Longstaff's statistical correction of the figures adduced shows, as Dr Ransome remarks, that the proportion is not greater than would result from merely accidental coincidence.

Italy consumption has always been regarded as a contagious disease. The demonstration of the presence of the bacillus of tubercle in cases of phthisis affords a ready explanation of its being communicable. That it is not readily communicated is certain, but it does seem to be so under certain favourable conditions, as in the case of husband and wife and other persons living in close and habitual contact. The dried sputum of phthisical persons preserves the bacillus for a long time, and in crowded towns there must be abundant opportunities of infection from so common a disease.

There is also reason to believe that the tubercular contagion may be conveyed by means of milk from diseased cows, and may thus gain entrance directly to the intestine and indirectly to the lungs (cf. *supra*, p. 316). The same property has been ascribed to imperfectly cooked meat from tuberculous cattle, but with less evidence at present. A Royal Commission on this important subject is about to begin its inquiries (July, 1890).

ii. *Habitual breathing of air rendered impure by overcrowding or by defective ventilation* may, and probably does, act in two ways: first, indirectly by weakening the resistance of the tissues; and secondly, directly, by increasing the chance of infection. The organic matter exhaled during respiration appears to be directly poisonous. Dr Parkes cites some experiments made by Gavarret and by Hammond with expired air from which the carbonic acid and water had been removed, so as to leave only the organic matter; a mouse placed in it died in forty-five minutes. Dr Parkes says that he has known instances in which breathing for three or four hours air contaminated by having been previously used in respiration, caused headache and febrile symptoms which lasted one or two days. It is important to remember that such organic substances probably differ from gases like carbonic acid in having far less tendency to rapid diffusion through the atmosphere; they readily adhere to textile fabrics, especially to those which are dark-coloured, and cling to them obstinately. Every physician is familiar with the peculiar odour belonging to the clothes of the women and children of the poorer classes; one perceives it as soon as they enter the out-patient room. Precisely the same smell is constantly to be perceived in the rooms in which these people live. The organic matters which cause it cannot be removed by merely causing a current of air to blow through a room for a few minutes in the day; still less will they escape through a door towards which there is no active draught. In all probability the only way of getting rid of them is by oxidation; and possibly the agency of ozone is likely to destroy them more rapidly in full sunlight.

Strictly speaking, overcrowding and defective ventilation are not convertible terms; but in practice we scarcely ever meet with one of them apart from the other. It is possible no doubt for one person occupying a room of good size so to close up all the openings as to render the air impure. But there is never overcrowding without bad ventilation, because when many persons are huddled together in a small space the needful admission of fresh air exposes some of them to cold draughts, and is sure to lead to one aperture after another being shut up.

The proof that impure air is a cause of phthisis rests mainly upon the evidence of statistics as to the frequency of the disease among soldiers, artisans, and inmates of prisons. As regards soldiers, a Royal Commission upon the Sanitary Condition of the Army, which reported in 1858, brought to light the fact that the death-rate from consumption in all branches of the service was in excess of that of the civil population of large towns, and

(what was most remarkable) that among the Foot Guards it was more than twice as great as that of the civil population. The only explanation that could be offered was that it came from defective barrack accommodation, since neither the clothing of the soldier, nor his food, nor the nature of his occupation could be supposed to be the cause of it. There was evidence that in barrack dormitories the cubic space actually given to each man was often not more than one half or two thirds of the amount of 450 feet, which was the minimum allowed by regulation; and it was also shown that the air in these rooms became offensive before morning. The conclusion at which the Commission arrived has since been confirmed by the great fall in the consumptive death-rate, especially among the Foot Guards, which has followed the introduction of sanitary improvements.

Dr Farr long ago stated his belief that the prevalence of phthisis in the armies of Europe is probably due in part to the inhalation of expectorated tubercular matter dried, broken up into dust, and floating in the air of close barracks.

In Dr Ransome's Milroy Lectures it is stated that in Canada, a country comparatively free from phthisis, the death-rate among English soldiers was 23 per 1000, compared with an average throughout England of less than 10 per 1000, and a death-rate in Manchester of only 12·4. After the barracks had been properly drained and ventilated, the mortality had sunk from 23 per 1000 in 1865 to 9·5 in 1872, and 6 in 1874.

As to workmen, we have evidence given by Dr Guy before the Commission of Inquiry into the State of Large Towns, of which the Duke of Buccleugh was president, and which reported in 1844. Dr Guy had most elaborately investigated the relative liability to phthisis of different classes of the population of London. He found that the disease was more fatal to artisans than to tradesmen, and more fatal to tradesmen than to professional men and the upper classes. Even hawkers, standing about in the streets and exposed to all inclemencies of weather, had the advantage over men employed in workshops. Among printers he instituted a very close comparison as to the frequency of symptoms of lung disease, arranging the men in classes according to the amount of air-space in the rooms in which they worked. Of 104 men having less than 500 cubic feet of air to breathe, 13 had suffered from blood-spitting and 13 others from catarrh; of 115 men having from 500 to 600 cubic feet of air, 5 had suffered from blood-spitting, 4 from catarrh; of 101 men having more than 600 cubic feet of air, 4 had suffered from blood-spitting and 2 from catarrh.

With regard to prisoners, there is the contrast between two prisons in Vienna, cited by Dr Parkes in his 'Practical Hygiene.' In the Leopoldstadt prison, which was very badly ventilated, there died in the years 1834—1847, 378 prisoners out of 4280, or 86 per 1000; of whom no fewer than 220, or 51·4 per 1000, died from phthisis. In the well-ventilated House of Correction in the same city there were from 1850 to 1854, 3037 prisoners, of whom 43 died, or 14 per 1000; and of these 24, or 7·9 per 1000, died of phthisis. Diet and mode of life were, it is believed, the same in both establishments. It is a flaw in the case that the average length of the periods during which the prisoners were detained in each prison is not given; but Dr Parkes thinks that no correction on this ground, even if needed, could account for the discrepancy in the death-rate. The great prevalence of phthisis among prisoners in general was long ago pointed out by Dr Baly, as the result of an examination of the 'Records of the Millbank Peni-

tentiary.' But he was unable to determine what part in the ætiology of the disease should be assigned to defective ventilation, and what to other depressing causes.

Indeed, it is obvious that only in very exceptional instances can overcrowding or defective ventilation be so isolated from other injurious conditions, apart from direct contagion, as to be proved the main cause of phthisis. For example, an important investigation was made by Dr Greenhow in 1860 and in 1861 as to the origin of the great mortality from phthisis among the workpeople employed in many of the largest industrial occupations of the country, and he found that the inhalation of dust of various kinds is the main cause of the disease so far as these persons are concerned (p. 1092). But Dr Greenhow himself pointed out that another cause was certainly the "working in ill-ventilated or over-heated factory rooms or workshops, as in those of some of the silk mills of Coventry, in the domestic weaving shops, and in the watchmakers' factories and workshops of the same city, in the button-makers' and various other workshops of Birmingham, in the factory rooms of Blackburn and Nottingham, and in many domestic shops and warehouses." Abundant details in support of this conclusion are to be found in the report which he furnished to Mr Simon.

iii. *Inheritance* is the most important predisposing cause of phthisis.—It is a matter of universal experience that in some families deaths from phthisis occur, generation after generation, with terrible frequency. Parents and their offspring are swept off in turn, so that sometimes there is hardly a survivor to maintain the stock. Actuaries are so impressed with these facts that whenever it can be ascertained, in reference to a candidate for life insurance, that he has lost a parent or more than one brother and sister from consumption, it is held at almost all offices that an addition to the premium is absolutely necessary to cover the increased risk; and if both parents have died of phthisis, or more than two other near relatives, the "life" is generally regarded as almost uninsurable on reasonable terms. It might at first sight appear strange that an augmented liability to what is (after all) only one among a great many other possible causes of death should be taken as diminishing to so great an extent the general "expectancy" of the candidate, but the requirements of the offices are in practice found to be fair and equitable.

From a scientific point of view, however, the question of the inheritance of consumption requires far more consideration than has generally been given to it. Among persons actually affected with phthisis, the proportion of cases in which the occurrence of a like disease can be traced in their relatives appears from certain investigations made by Dr Theodore Williams, and recorded in the 'Med.-Chir. Trans.' for 1871, to be 48·4 per cent. The patients were seen in private practice, so that the results are probably as little inaccurate in the way of omission as can be expected in such inquiries, although it would be an advantage, for the purpose of comparison, if we knew to what extent a similar family history exists in the population generally. But it is impossible to accept the figures given by Dr Williams, or any similar figures, as indicating in a scientific sense the extent to which consumption is transmitted by inheritance. The difficulty is often brought out very clearly by proposers for life insurance. A candidate has had perhaps two or three brothers who were consumptive, but one, he says, brought on the disease by dissipation and intemperance; another was in the army, and was stationed first in India and then in Canada at a few months'

interval; a third may have got a chill in bathing; and he winds up by declaring that phthisis has not been a "family complaint" after all. Now, among the cases collected by Dr. Williams, 484 in number, in which phthisis was traced among the relatives of patients themselves phthisical, there were 120 in which the disease had existed in one or both of the parents, but 224 in which it affected only brothers or sisters. There can be no doubt that if inquiries had been made as to the existence of definite "exciting causes" of the disease in these cases they would have been found to be very often present. It is, in fact, impossible to draw a line anywhere between what might be called respectively "hereditary" and "accidental" phthisis. Probably there are few families in which the consumptive tendency is so strong that it could not be kept in abeyance by hygienic precautions if they were thoroughly and vigorously carried out; and, on the other hand, there are very few families, if any, in which the disease may not show itself in such members of it as systematically neglect their health, or are exposed year after year to unfavourable circumstances.

It is impossible at present to determine in what proportion of cases the so-called "family predisposition" to consumption implies the actual transmission of a definite tendency to this disease, and in what proportion of cases it is merely the expression of a general delicacy of constitution (or, as the Germans call it, "vulnerability"), which renders those who are derived from certain stocks liable to be attacked by consumption in succession, as they happen to come under conditions suitable to its development. From the point of view of the insurance offices the distinction is not material, for in either case the demand for an enhanced premium is equally justifiable. One fact which tells strongly in favour of the opinion that family predisposition is often a mere vulnerability is that the liability to consumption is believed to be much above the average in those who come from parents already failing in health from any cause, in those begotten by a father advanced in years, in those born of a very young mother, and also in the later offspring of a woman exhausted by frequent and rapid child-bearing. Moreover, there is little evidence of a specially strong tendency to phthisis in the children of parents actually consumptive, one or both of them, at the time of procreation.

The experience of insurance offices as well as of private practice is that a phthisical tendency is more frequently transmitted by the mother than by the father.

iv. *Personal predisposition.*—It is a very old belief that persons of a particular bodily frame and physiognomy are prone to tuberculous diseases; and this has been called a *diathesis*. Little value, however, can be attached to the statements of early writers on the subject, because "scrofula," as it was called, was often confounded with rickets or with congenital syphilis; and, according to Sir Thomas Watson, the numerous signs of the "scrofulous diathesis" varied widely with the "temperament" of the individual, whether "nervous," "sanguine," or "bilious." All this was very confusing; and it seemed a step in advance when Sir William Jenner, in 1860, proposed to distinguish two *diathetic states*—tuberculosis and scrofulosis.

As leading features of *tuberculosis* he gave the following:—"Nervous system highly developed; mind and body active; figure slim; adipose tissue small in quantity; organisation generally delicate; skin thin; complexion clear; superficial veins distinct; blush ready; eyes bright, pupils

large; eyelashes long; hair silken; face oval, good-looking; ends of long bones small, shafts thin and rigid; limbs straight. Children the subjects of tuberculosis usually cut their teeth, run alone, and talk, early."

He described *scrofulosis* as follows:—"Temperament phlegmatic; mind and body lethargic; figure heavy; skin thick and opaque; complexion dull, pasty-looking; upper lip and alæ of nose thick; nostrils expanded; face plain; lymphatic glands perceptible to touch; abdomen full; ends of the long bones rather large; shafts thick."

Among the pathological tendencies of the former morbid conditions he mentioned not only "deposits or formations of tubercles," but "fatty degeneration of liver and kidneys, and inflammation of the serous membranes." To the latter he assigned "inflammation of the mucous membranes of a peculiar kind; so-called strumous ophthalmia; inflammation of the tarsi; catarrhal inflammation of the nose, pharynx, bronchi, stomach, and intestines; inflammation and suppuration of the bronchial glands on trifling irritation; obstinate diseases of the skin; caries of bone."

Many physicians still believe that Jenner's descriptions correspond with two great types, the recognition of which is really important in practice. But this belief is incompatible with modern views as to the relation between tubercle and caseating affections of lymph-glands; no less incompatible with Buhl's theory of infection than with the more recent demonstration that the glandular affections are themselves tuberculous.

Moreover, though many of those who die of phthisis present the characters, according to Jenner, of scrofula, a much larger proportion have no such indications; while his description of tuberculosis seems to refer to a habit of body which, while not incompatible with symmetrical growth and physical beauty, shows a want of power of resistance to disease in general, rather than to the invasion of tubercle in particular.

Mr Francis Galton and the late Dr Mahomed recorded in the 'Guy's Hospital Reports' for 1881 the results of "An Inquiry into the Physiognomy of Phthisis by the Method of Composite Portraiture." Their conclusions seem to bear out the view just stated. For although they were able to obtain from the photographs of 442 phthisical patients two types of face—the one of narrow ovoid shape, the other a broad face with coarse features,—yet this was only by the careful selection of a few out of the whole number; and they found a larger proportion of narrow ovoid faces among patients who were not phthisical than among those who were.

The fact is that the words *scrofula* and *struma* have been applied in so loose and arbitrary a way, quite independently of chronic swelling of the cervical lymph-glands, or even of evidence of caseous disease in any part of the body, that it is better to avoid their use until we have a collection of facts based on the accurate use of clinical or pathological terms. Moreover, tendencies to scrofula or tubercle which are never carried out can scarcely be the subject of useful discussion, nor can the exploded doctrine of temperaments be revived until we again accept the four Galenical humours and their eucrasia or dyscrasia.

The phthinoid chest.—There still remains the question whether a tendency to phthisis is indicated by any particular *form of chest*. Dr Gee recognises two shapes of chest in persons predisposed to consumption.

One of them is the "alar," or "pterygoid" chest of Galen and Aretæus. This is narrow and shallow, the antero-posterior diameter being especially small, and the angles of the scapulæ projecting like wings; its peculiarities

depend upon drooping or increased obliquity of the ribs, as the result of which the shoulders fall and the length of the thorax from above downwards is increased; the alar or "winged" appearance is caused by the projection of the scapulæ. The throat is often prominent, the neck long, and the head carried unduly forwards.

The other is called the "flat" chest; this, instead of being rounded, is flattened in front, the rib cartilages losing their curve and becoming straight; or the sternum may actually be depressed below the level of the costal ends of the cartilages. Persons who are extremely flat-chested often have broad shoulders, so that, as one stands facing them, one might fancy them to be by no means ill developed. Traube and other German writers lay great stress on the significance of a flat chest as indicating a liability to consumption, and Dr Wilks used to insist on it strongly.

But probably the "flat chest of phthisis," like the "rounded chest of bronchitis," is an acquired condition, the *result of disease*, not the indication of its future advent. Neither the alar nor the flat chest is seen in early phthisis with more frequency than other varieties of ill-shapen chest, which often result from neglect during childhood, and are consequently very common among the poorer classes.

Again, one cannot dissociate congenital from acquired deformities of the thorax in regard to their possible influence on the subsequent occurrence of tubercular disease of the lungs. Freund, in 1859, maintained that what caused a small and contracted chest was often a premature ossification of the cartilage of the first rib, occurring even in early infancy. It is worthy of notice that Dr Hutchinson, in advocating the use of the spirometer, did not suggest that a defective vital capacity of the lungs indicated a tendency to phthisis, but rather that it was a sign of the actual presence of the disease at an early stage. Again, deformity of the chest from lateral curvature seems certainly not to carry with it any increased liability to consumption. It appears to be very doubtful whether the habit of stooping at a desk, or in the work of a tailor or shoemaker, or weaver, although it cannot but be injurious to the health, specially favours the development of phthisis. Nor is there evidence that the foolish practice of compressing the base of the chest by stays is capable of producing such an effect.

iv. *Predisposition from general causes.*—The following deteriorating influences lead only indirectly to phthisis, by weakening the health and the power of resistance of the tissues.

Food insufficient in quantity and bad in quality is assumed to predispose to phthisis, but it would be difficult to adduce any positive proof of this.

The same doubt applies to the presence of *anæmia*. Certainly both emaciation and anæmia may go on to an extreme degree in hospitals where cases of phthisis are present, and yet no tubercle develops.

Child-bearing and suckling seem often to be concerned with phthisis in women. It is a well-known and remarkable fact that during gestation, consumption is scarcely ever fatal. The patient survives until labour is over, after which the symptoms become more urgent than ever, and death may follow rapidly. In many cases the disease appears to begin during lactation, or after profuse puerperal hæmorrhage. Cases associated with child-bearing generally run a particularly acute course.*

* These considerations are so important in regard to life insurance, that it is only prudent to count all deaths of mothers "in childbed" or "after delivery" as due to phthisis, unless there is explicit evidence of previous good health.

Alcoholic intemperance has a doubtful position in the ætiology of phthisis. Clinical experience shows that drunkards die in large numbers of this disease; but it is often difficult to exclude the operation of other causes, such as bad ventilation, and exposure to cold and wet. Moreover, some writers have believed that the moderate and even the excessive use of alcohol is rather prophylactic against than productive of phthisis. Observations in the United States have been cited in favour of this view. Dr Walshe and Dr Wilks do not accept intemperance as a cause of consumption, while Dr Williams has no hesitation in doing so. Lately Dr Owen, of St George's Hospital, found that, among the phthisical patients attending there, 50 per cent. were, on their own showing, excessive drinkers, while only 33·5 per cent. of the other patients confessed to habits of intemperance; or, put in another way, of 100 non-consumptive patients, 41·5 professed to be temperate; of 100 consumptives, only 23.

It must be remembered that drunkenness goes with poverty, exposure, and unhealthy living, which are acknowledged to be predisposing causes of bronchial and alveolar catarrh and so of phthisis. Again, most of the publicans, barmen, and other intemperate classes who consult a specialist will be subjects of the disease for the treatment of which he is esteemed. Is phthisis less common in Italy than in Great Britain, in Constantinople than in Glasgow? Are total abstainers more exempt from consumption than temperate persons? And do no intemperate persons recover from phthisis? These are questions not yet answered.

It has often been supposed that phthisis in drunkards is usually fibroid rather than tuberculous. Huss, of Stockholm, suggested this opinion about 1850, and it has been supposed to derive support from the fact that alcohol causes a growth of interstitial fibrous tissue in the liver, and perhaps also in the kidneys and elsewhere throughout the body. But it is certain that tubercular peritonitis of the most typical kind is often seen in intemperate persons who also have hepatic cirrhosis. We have given reason to believe that "fibroid phthisis" is not essentially distinct from the more purely tubercular form of the disease, but is only the extreme type of what almost every case of phthisis shows in some degree, a power of repair by cicatrisation, adhesions, and fibroid thickening. Moreover, the diagnosis of fibroid phthisis which during the life of the patient had been partially based upon a history of alcoholic intemperance, has been repeatedly falsified by the autopsy.

Diabetes is a frequent cause of a phthisis which is peculiarly pneumonic in character; its relations to tubercle are still disputed. This point will be discussed in the chapter on Diabetes, but here the probability may be stated that the diabetic affection of the lungs is an acute variety of tuberculous phthisis.

Syphilis is sometimes followed by the development of a destructive disease of the lung, which on *post-mortem* examination is found to be typically tuberculous. No fewer than thirteen cases of this kind occurred at Guy's Hospital between the years 1863 and 1873. But one must not forget that among syphilitic patients, especially in hospital practice, many are intemperate, destitute, and every way careless of their health. Consequently it is quite possible that the relation between the phthisis and the syphilis may, in many of the instances just referred to, have been one of mere coincidence. Or it is possible that the cachexia of syphilis may favour the development of tubercle in the same way as it leads to lardaceous disease of the viscera and to tabes dorsalis. The administration of iodide of potassium is occasionally

followed by striking improvement in the physical signs and symptoms of what had appeared to be phthisis in a syphilitic subject, or even by their complete subsidence. It is true that any treatment which improves the general health of a consumptive patient may be followed by an apparent cure of the pulmonary affection; but a more probable way of explanation of the striking action of antisyphilitic remedies in the cases in question is to recognise a syphilitic disease of the lungs capable of simulating phthisis, but pathologically distinct. The characters of such a disease, distinct from true or tubercular phthisis occurring in a syphilitic subject, have been set forth in the chapter on chronic inflammations of the lungs (*supra*, p. 1011).*

The following conditions affect the lungs directly, and act as predisposing causes of phthisis by producing precedent catarrh.

vi. *Inhalation of dust.*—Ramazzini, in his work, 'De Morbis Artificum,' published in 1703, seems to have been the first to point out that certain classes of workmen are liable to have their lungs injuriously affected by dust given off by the materials which they employ. In the present century the question has been studied very thoroughly, especially in England and in Germany; and Zenker has proposed to term the pulmonary diseases due to this cause *Pneumonoconiosis* (κόνις = dust). The nature of the mischief set up in the respiratory organs by breathing dust varies widely in different cases. It may be a mere catarrh of the trachea and bronchial tubes, leading to chronic cough and emphysema, and perhaps proving fatal by dilatation of the right side of the heart and dropsy. But in many instances it consists in consolidation of the lung, which may ultimately lead to the formation of cavities, and spread through the pulmonary tissue from apex to base, as in other cases of phthisis; so that it has been usual to speak of "miners'," "weavers'," and "knifegrinders' consumption." Pathologists, however, almost without exception maintained that the lesions found in such cases were not tuberculous. Whether tubercle was regarded as a deposit from the blood in a special dyscrasia, or as a particular kind of new growth, it seemed equally logical to deny the possibility of its being due to a mere local irritation of the tissues. These views were of course

* There is, of course, no reason why gummata should not develop themselves in the lung as well as in any other organ; but the recorded instances in which such lesions are stated to have been found in the *post-mortem* room seem to me to be generally open to more or less doubt. Take, for example, Dr Goodhart's case, of which there is a coloured plate in vol. xxx of the 'Pathological Transactions.' He himself mentions that Dr Reginald Thompson considered the supposed gummata to be relics of pulmonary hæmorrhage (*loc. cit.*, p. 236), and they certainly do not seem to me to differ at all from the encapsuled cheesy masses which are often found in ordinary cases of phthisis. Moreover, one cannot admit in the present state of pathology that the undoubted grey tubercles which also existed in large numbers in Dr Goodhart's case were merely secondary results of the caseation of gummata, causing infection of the pulmonary tissue, although a few years ago such an interpretation of the facts would to most observers have appeared satisfactory. In vol. xxviii of the 'Pathological Transactions' may be found a detailed discussion of the relations between syphilis and phthisis by Dr Goodhart (pp. 313—329); and there are also cases in which the lungs appeared to contain syphilitic lesions, recorded by Dr Pye-Smith and Dr Green (*ibid.*, pp. 331, 334). But I fail to discover, either there or anywhere else, such examples of extensive lung disease, obviously and unmistakably different from tubercular phthisis, as certainly ought now and then to be met with if the views held by these observers were correct. Dr Moxon, when pathologist at Guy's Hospital, was much impressed with the fact that in several syphilitic cases he found in the lungs indurated patches, the centres of which had sloughed away so as to form cavities in the interior of which shreddy masses were still hanging. And I think that he came to the conclusion that such appearances were almost characteristic of a syphilitic affection. But the difficulty is that they are altogether unlike those which syphilis is known to produce in other organs.—C. H. F. (1880).

adopted by those who accepted Niemeyer's doctrine of the non-tubercular nature of phthisis in general. And the theory of the local development of tubercles, as the result of tissue-infection from lesions themselves inflammatory, seemed to remove all difficulties by explaining the fact that in many cases the more recently affected parts of the lungs show tubercles when none can be discovered in the parts which were earliest diseased.

It might be thought that the reports of autopsies could decide the matter, since they generally affirm that the appearances found in the lungs are altogether different from what are seen in tubercular cases. But several points must be borne in mind. One is that the character of the lesions in the lungs is often greatly obscured by the discoloration from the foreign particles deposited in the pulmonary tissue. Another is that as a rule the destructive diseases of the lungs which are due to inhalation of dust occur at rather a late period of life, and advance slowly to a fatal termination; in both respects they resemble that form of phthisis which is regarded by many pathologists as distinct from the tubercular, and termed fibroid. In descriptions of the diseased lungs of miners, potters, or stoneworkers, the use of the word tubercle is carefully avoided; but mention is often made of "nodules," from the size of a millet-seed to a pea, scattered in the pulmonary tissue, of an opaque, greyish-yellow colour, and perhaps with a small central cavity. The microscope is called in to prove the negative fact that the nodules in question fail to present whatever histological structure may happen to be regarded as characteristic of tubercle at the time when the observation is made; or possibly it is asserted that they are distinguished by their hardness and resistance to pressure, the fact being overlooked that undoubted tubercles, if they fail to caseate, undergo conversion into precisely similar bodies. Anatomically the chronic pneumonia of grinders and potters cannot be separated from chronic tubercular phthisis.

Nor does it appear that the clinical course of the disease due to dust-inhalation differs essentially from that of the more chronic forms of phthisis. Dr Greenhow, who was one of the leading authorities on the subject, insisted (in the 'Pathological Society's Transactions,' vol. xvi, p. 61, *et passim*) on "the coincidence of a cool skin and a quiet pulse with wheezy asthmatic cough and copious muco-purulent expectoration," as rendering "the diagnosis from tubercular phthisis comparatively easy." And elsewhere he says that "shortness of breath almost invariably precedes by some considerable time the appearance of cough, and the patient is often ailing for many years before being disabled from work." But with regard to the suggestion that the early dyspnœa is distinctive, it must be remembered that bronchitis and emphysema are marked effects of the inhalation of dust. Moreover, it is possible, as Seltmann suggested in the 'Deutsches Archiv' for 1867, that when foreign matters are deposited in the lungs in large quantity the respiratory surface may be so much diminished that dyspnœa is a result.

Lastly, recognition of the presence of Koch's bacilli has conclusively established the tuberculous nature of the disease, and confirmed, in several cases of pneumonoconiosis, the justice of the opinions above expressed.*

* Bacilli were found in two cases of grinders' phthisis at Brompton Hospital kindly communicated to the writer by Dr Theodore Williams, and in three cases of potters' phthisis, published by Mr Watson Cheyne in a valuable paper on the "Relation of Micro-organisms to Tuberculosis," in the 'Practitioner' for April, 1883 (p. 294).

The materials which give off dust that may enter the respiratory organs are of various kinds. They may be classified as follows.

(1) *Particles of carbon.*—As far back as 1813 Pearson, in the 'Philosophical Transactions,' threw out the suggestion that the black discoloration of the lungs and of the bronchial glands, which is found in most adults, but not in children, consists of particles of carbon "introduced with the air in breathing," and originally "derived from the combustion of coal, wood, and other inflammable materials." A similar opinion was expressed by Laennec. In 1831 Dr Gregory recorded the case of a labourer in the coal mines of Dalkeith; both lungs were throughout of a uniform coal-black colour, and yielded, when washed, a dark matter, which was found by Dr Christison to resist the action of concentrated nitric acid and of chlorine, and to yield by distillation products just like those which result from the distillation of coal. The conclusion seemed irresistible that the organs had been discoloured by the penetration of coal-dust from without. "Spurious melanosis," therefore, and *Anthracosis*, proposed by Stratton in 1837, were the terms applied to this condition of the lungs. But Hasse in 1841, and Virchow in 1847, gave reasons for doubting this explanation, and it was not until 1860 that a case was recorded by Traube in the 'Deutsche Klinik,' which finally established the reality of anthracosis. The patient was a man who for about twelve years had been engaged in loading and unloading wood-charcoal. He had long been accustomed to expectorate a black substance, and when he died his lungs were found to be almost everywhere of a black colour, yielding to pressure a black frothy fluid which stained the fingers like thin Indian ink. Both in the sputa, and in the pulmonary tissue, there were found minute foreign bodies of irregular form, with pointed processes. That these were fragments of wood-charcoal was evident not only from a comparison with particles of the charcoal brought from the place where the man had worked, but also from the fact that some of them showed the circular discs characteristic of the woody fibres of Coniferæ. A second similar case came before Traube six years later, but even he did not at first admit from these two cases that the finely granular material which gives a black colour to healthy lungs as life advances is also inhaled carbon. This conclusion was greatly helped by Zenker's discovery that the lungs of those who work with red oxide of iron become full of red particles. In 1866 Virchow took an opportunity of recanting his former views, and Rindfleisch in his 'Handbook' ascribes anthracosis to the cause denoted by the word.

Modern histology has removed one of the greatest obstacles in the way of the acceptance of this doctrine, by showing that leucocytes are capable of taking particles of foreign materials into their substance, and that animal membranes are permeable in a way that formerly was unsuspected.

In 1858, in describing in the 'Edinburgh Medical Journal' a specimen of "miner's lung" which had been sent to him from Scotland, Virchow had stated that scarcely any of the black matter was found in the interior of the alveoli; and in their walls it lay not beneath the endothelium, but between the elastic fibres and the connective tissue. It was still more abundant in the interlobular and peribronchial fibrous tracts, and beneath the pulmonary pleura. It may even be present in the costal and diaphragmatic pleura, as well as in the bronchial glands. At Guy's Hospital we once found some of it free in the upper and back part of the pericardial space, separated by the fibrous wall of the sac from an intensely black gland that lay just outside. The distribution of inhaled particles of dust has been studied

experimentally by von Jus, whose observations are recorded in the 'Arch. f. exp. Pathologie' for 1876. He injected cinnabar into the air-passages of dogs, and found that the particles were rapidly taken up by cells which he believed to be altered leucocytes, so that five days later scarcely any pigment was left in the pulmonary alveoli; within six hours after the commencement of the experiment some of it reached the bronchial glands, being first deposited in their cortical layer, but ultimately reaching their medullary structure; much, however, remained in the lungs, being accumulated in the connective tissue, between the lobules, round the vessels and the tubes, and beneath the pleura. In other words, von Jus found that its distribution corresponded precisely with what had been described by Virchow in the case of the miner's lung.

The phthisis associated with anthracosis is attended with one special symptom, which may be conveniently mentioned here. This is the "black spit" which is often ejected in considerable quantities and for a long time, even by miners who have entirely ceased to follow their occupation. There is no doubt whatever that it is often due to the gradual disintegration of the blackened and infiltrated parts of the lungs, or comes from vomicæ such as are sometimes found after death, full of a black liquid. Thus, Dr Greenhow showed to the Pathological Society in 1869 the lungs of a collier who about ten days before his death suddenly spat up matter closely resembling black paint, and continued to expectorate four or five ounces daily until he died; in the right lung there was a large irregular cavity, containing a quantity of black pulpy residue. Nevertheless sputa may be very black without there being any lesion of the pulmonary tissue beyond the anthracosis; hæmoptysis or the detection of elastic tissue or of bacilli in the sputum is needful to prove that ulceration is going on.

(2) *Oxide of iron.*—In 1864, in discussing the subject of anthracosis, Friedreich asked the question why, if the black lungs and bronchial glands of coal-miners were due to inhaled carbon, the workers in red sandstone quarries should not have the corresponding organs reddened by the dust to which they were exposed. Now, it happened that Zenker had at that very time in his possession the lungs of a woman who had, for seven years before her death, been engaged in making the little paper books in which gold-leaf is laid. The paper has to be coloured red with peroxide of iron, and this is rubbed in with a piece of felt. The occupation is a very dusty one; and the woman's lungs were found after death to be throughout of a bright brick-red colour, so that their cut surface looked just as if it had been daubed over with red paint. The microscope showed that granules of oxide of iron were present, beneath the pleura, in the interlobular fibroid septa, in the peribronchial sheaths, in the walls of the alveoli, and even in cells occupying their interior. In the twentieth volume of the 'Pathological Transactions' there is a coloured drawing of a section of this lung, taken from a specimen in the possession of Dr Wilson Fox; the tint is much browner than in Zenker's drawings published in the 'Deutsches Archiv' two years before. Zenker proposed to name the affection Siderosis (σίδηρος = iron). In 1874, Merkel, in 'Ziemssen's Handbuch,' was able to refer to seven other cases, one of which followed the use of red oxide of iron for polishing glass. He had also met with two instances in which the lungs were blackened by the black oxide of iron, and one in which ferric phosphate was present. There was no difficulty in detecting the iron in the sputa by hydrochloric acid and ferrocyanide of potassium.

(3) *Silica and alumina.*—It has long been known that workmen whose occupations expose them to siliceous or argillaceous dust are very prone to die of phthisis. Very full information with regard to the excessive mortality from this cause in certain districts of England is contained in a paper by Dr Greenhow in Mr Simon's third 'Report to the Privy Council,' published in 1861. Merkel proposes to term the resulting disease of the lungs *Chalicosis* (χάλιξ = gravel). The presence of silica in the pulmonary tissue seems to have been first detected chemically by Dr Peacock and by Dr Greenhow. Kussmaul, however, has since shown (in vol. ii of the 'Deutsches Archiv') that this substance is present in greater or less quantity in the lungs of all persons (though not in those of a fœtus), having doubtless been derived from the dust of the streets and roads blown up by the wind. In a railway signalman, stationed in a very sandy district, Meinel found that silica actually formed as much as 18·2 per cent. of the ash of the lungs after incineration; even in a stonemason who died of phthisis, and whose lungs were analysed by Kussmaul, the amount was not greater than 24·7 per cent. of the ash. Under the microscope the particles of silica may be seen as bright bodies of round or angular shape.

Among artisans who suffer from this cause are, of course, *stonemasons*, lithographers, and millstone makers. Still more fatal is the grinding and polishing of steel instruments—from scythes to needles—such as is carried on in Sheffield and Birmingham. Whether the exact nature of the work be needle-pointing or fork-grinding, or the sharpening of fish-hooks, the result differs but little; a large number of the men die prematurely, some between twenty and thirty, and more between thirty and forty: very few survive the age of forty without suffering more or less from pulmonary symptoms. This has been long known at Sheffield as "grinders' rot." What is termed "dry-grinding" is much more injurious than "wet-grinding;" for in wet-grinding the wheel, as it revolves, dips into water and deposits a large part of the dust which would otherwise be carried into the air. But even wet-grinders are greatly exposed to dust in "hacking" their grindstones, which generally has to be done every day.

Potters, again, are exceedingly apt to be attacked with phthisis; "flat-pressers" suffer more than "hollow-pressers;" but the worst off of all are "china-scourers," whose business is to rub off the loose flint powder from the china with sand-paper, after it has been baked. Another dangerous occupation is pearl-shell cutting.

By the use of respirators, and by other preventive means, the terrible mortality in these trades has of late years been happily reduced.

(4) To the occupations which lead to injury from the inhalation of vegetable matters must be added the carding of *cotton*, and the hackling of *flax*. In two men who had worked in a *tobacco factory*, Zenker found "brown spots in the lungs and in the bronchial glands, evidently due to the deposition of powdered tobacco."*

Pathology of these pneumonoconioses.—It is clear, then, that foreign particles of various kinds may find their way into the lungs, may be deposited in the pulmonary tissue, and may either remain there or be ultimately transported to the bronchial glands. But it by no means follows, as a matter of course, that their presence must be injurious. Indeed, since the true nature of the

* According to Hirt's tables of mortality from phthisis in various trades in Germany (quoted by Dr Ransome) the highest death-rate is among flintworkers and filecutters, then come grinders and stonecutters, next brush-makers, and then cigar-makers and glasscutters.

black material found in the lungs, whether in health or in disease, has of late years become established, increasing doubts have been expressed as to whether it can fairly be regarded as the cause of inflammatory or destructive changes. In Traube's first case, referred to above, there was not the slightest trace of any newly formed connective tissue nor of any induration of the substance of the lungs; the patient's symptoms were probably due to chronic pericarditis, accompanied by double pleurisy. Seltmann, of Zankeroda, near Dresden, asserts positively in the second volume of the 'Deutsches Archiv' that among the coal-miners of that district there is generally no overgrowth of connective tissue whatever, even in lungs full of black deposits, and that the formation of cavities is very rare. As for tuberculosis, he thinks that the inhalation of carbon is actually antagonistic to its development—an opinion which Merkel appears to share.

If, therefore, English miners are peculiarly liable to destructive disease of the lungs, the explanation may be that the galleries in which they work are so often badly ventilated; the real cause of their being attacked with phthisis is not that the air which they breathe contains coal-dust or smoke, but that it is rendered impure as in crowded workshops or sleeping-rooms. Indeed, in his fourth report, Mr Simon drew special attention to the fact that the colliery miners of Durham and Northumberland differ from other miners in not suffering from any important excess of pulmonary disease, and argued that the reason for this is the good ventilation of the mines in which they work; but he was still disposed to think that this operated mainly by removing the coal-dust and powder-smoke. The great heat to which miners are exposed is probably another factor in the ætiology of the pulmonary diseases to which they are liable.

On the other hand, there is no doubt that destruction of the pulmonary tissue is the result of the entrance of other kinds of foreign particles into the lungs. Merkel says that in his cases of siderosis fibroid changes were never wanting, even when the patient had died of some independent disease. And among needle-grinders, potters, and other classes of workmen exposed to the inhalation of flint-dust or finely-powdered clay the prevalence of phthisis is far too great to be accounted for in any other way. The only opportunity which Merkel ever had of examining a grinder's lung was in the case of a boy aged sixteen, who was accidentally killed after having worked at the trade four and a half years, when apparently in good health. His lungs already contained small, tough, black nodules, of the size of a pin's head, as well as minute particles of sandstone and of iron.

Whatever may be the nature of the irritant which sets up destructive changes in the lungs, the resulting affection appears to have exactly the same characters. This was strongly insisted on by Dr Greenhow, when in 1865–70 he successively showed at the Pathological Society's meetings the lungs of a collier, a copper-miner, a razor-grinder, a stone-worker, a potter, a flax-dresser, and a pearl-shell cutter. It is remarkable that the lungs may be almost if not quite as black in those patients in whom the affection was set up by sand or clay as in the miners themselves. The explanation is that bronchitis, by interfering with the natural ciliary action of the mucous membrane, causes the particles of carbon in dust and smoke, which in greater or less amount are inhaled by everyone, to become deposited in the pulmonary tissue, instead of being swept back into the trachea. But, further, when any destructive process is set up in a lung the affected parts are very apt to become more deeply blackened than the rest of the

organ. One of the points on which Virchow insisted when he upheld the view that the discoloration was due to a pigment derived from altered hæmatin, was that even in children the development of phthisis was sometimes attended with a blackening of the tissue which at their age could only be regarded as exceptional. The experiments of von Jus, referred to above (p. 1095), enable us to understand why the foreign material should accumulate in newly-formed fibroid tissue, and even in fibroid tubercles of a diseased lung, just as it does in the connective-tissue tracts of the healthy organ rather than in its alveoli.

The complete identity of the pulmonary affections to which so many different classes of operatives are liable is in itself sufficient to show that a common pathological process is concerned in producing them. Since the irritants which excite these several diseases act upon all parts of the lungs alike, the resulting lesions might be expected to be uniformly diffused. But, as a matter of fact, it is found that in most cases they attack one lung before the other; they almost invariably begin in the upper lobe, and spread gradually downwards through the organ towards its base—that is, they follow the characteristic distribution of phthisis.

vii. *Cold and wet.*—No idea is more firmly rooted in the public mind than that consumption is often the result of accidental causes, such as getting chilled by remaining in wet clothes, or by exposure to a draught when heated in dancing, or by sleeping in damp sheets; and generally that there is danger, especially in those who are hereditarily predisposed to the disease, of its supervening upon a cold, or a succession of colds. But the weight of medical opinion has in our day tended against such notions.*

The considerations which led pathologists to reject the idea that phthisis could arise out of a common catarrh were probably in the main identical with those which induced them to regard as necessarily non-tubercular the cases due to dust-inhalation. And such theoretical opinions were greatly strengthened by the practical observation that many persons, even of delicate aspect, suffer for years from an extreme liability to bronchial attacks without ever becoming consumptive. Indeed, Rokitansky believed that pulmonary emphysema and dilatation of the bronchial tubes, if carried far enough to cause venosity of the blood and cyanosis, afford exemption from the liability to pulmonary tuberculosis (cf. p. 1106).

But, apart from the crucial instance of congenital disease of the heart, there are striking exceptions to Rokitansky's rule. In 1864, for example, a girl of seventeen was admitted into Guy's Hospital with extreme dyspnœa and dropsy, and with clubbing of the fingers and toes. The bronchial tubes were found widened out into great sinous passages, so that the cut surfaces of the lungs showed hollow spaces as extensive as the remains of the pulmonary tissue. Yet there were scattered yellow tubercles, especially in the left lung, spreading from the apex downwards. In 1874 a woman, aged thirty, died, who had long been more or less subject to cough, which for nine months before had become continuous. There was extreme emphysema of the bases and anterior parts of the lungs, and the tubes contained a large

* The only statistical facts which are in favour of the popular view are those given by Dr Theodore Williams in vol. liv of the 'Med.-Chir. Transactions.' Out of 1000 cases of phthisis he found that no fewer than "149 had originated in, or been closely preceded by, pleurisy and pleuro-pneumonia, and 118 by bronchitis;" but probably this tabulation must have generally rested on the unsupported assertions of the patients themselves, who doubtless consulted him or his father, Dr C. J. B. Williams, at variable periods after their illness had begun, and often when a considerable time had elapsed.

quantity of pus; but both lungs also showed scattered grey tubercles and patches of translucent grey consolidation, with points of caseation breaking down here and there into cavities. There would be no difficulty in citing many similar cases from our *post-mortem* records were it needful.

Another fact which indicates that catarrh is apt to lead to phthisis is the frequency with which, in children, pulmonary tuberculosis follows whooping-cough or measles.

We certainly have no proof of the occurrence of what is so often spoken of—a primary catarrh of one or both of the apices. But if tuberculosis is a modification of the inflammatory process due to the presence of bacilli which are especially apt to attack the apices of the lungs, there is nothing improbable in the supposition that irritation of the whole of the pulmonary tissue by cold may set up phthisis there, while failing to do so elsewhere. More than one instance has come before the author in which consumption has appeared to be distinctly traceable to moving into a damp, newly built house, the patient having been quite well before.

Nevertheless, caution is required in accepting the statements of patients as to the origin of their illness. In 1869 a young man died of phthisis in Guy's Hospital, who attributed the disease to his having slept with his window open one night five weeks before. He admitted, however, that nine months previously he had been ill for a week with a cough. At the autopsy, beside very acute pneumonic phthisis, there were found at the left apex old clustered grey and black tubercles and cavities. This, therefore, could not be cited as a case caused by exposure to cold.

viii. *Damp soil.*—It is most probably by the increased liability to attacks of slight bronchial and pulmonary catarrh which must necessarily follow residence in damp situations, that we can account for certain remarkable facts with regard to the influence of damp and ill-drained localities upon the frequency of phthisis. In 1862 Dr H. I. Bowditch, of Boston, took occasion, in addressing the Massachusetts Medical Society, to bring forward a mass of evidence which led him to believe that, in that State, consumption, instead of being equally distributed, prevails especially in such places as are situated upon a damp soil, and seldom occurs when the soil is dry. This evidence consisted chiefly of an analysis of the replies of medical men living in 183 townships to inquiries as to the frequency of the disease in their practice, and as to the moisture or dryness of the localities. It also included some striking instances in which phthisis had carried off in succession a number of persons living in certain houses surrounded by wet meadows, or placed by the side of a millpond, or shut in by trees.

Far more conclusive, because resting upon an accurate statistical basis, is a body of facts which were collected by Dr Buchanan during the years 1865 and 1867 in England, and published in Mr Simon's ninth and tenth reports to the Privy Council. The inquiry began in a tour of inspection made for the purpose of ascertaining the results of sanitary works that had been carried out in twenty-five towns, containing an aggregate population of 606,186 persons. It was found that in several places there had been a great diminution in the general death-rate, and that the prevalence of enteric fever had become much less, especially where a good water supply had been substituted for a bad one, and where drainage works had displaced cesspools or middens. But in other towns it was by a decrease in the number of cases of phthisis that the good effects of sanitary improvements appeared to be manifested; and the particular change which coin-

cided with this result was found to have been drying the ground by drainage of the subsoil. The following table shows the amount of change in the death-rate from phthisis in twenty-four of the towns visited by Dr Buchanan:

Town.	Previous death-rate per 10,000 from phthisis.	Degree of change in death rate from phthisis.		Influence of sewage works on subsoil.
		In total population.	In females between 15 and 55.	
Salisbury	44½	−49 p. c.	?	Much drying.
Ely	32	−47 p. c.	?	Much drying.
Rugby	28½	−43 p. c.	−48 p. c.	Some drying.
Banbury	26⅔	−41 p. c.	−36 p. c.	Much drying.
Worthing	30½	−36 p. c.	−41 p. c.	Some drying.
Macclesfield	51½	−31 p. c.	−22 p. c.	Much drying.
Leicester	43½	−32 p. c.	−16 p. c.	Drying.
Newport	37	−32 p. c.	−13 p. c.	Local drying.
Cheltenham	28⅝	−26 p. c.	−25 p. c.	Some drying.
Bristol	33½	−22 p. c.	−18 p. c.	Some drying.
Dover	26½	−20 p. c.	−18 p. c.	Local drying.
Warwick	40	−19 p. c.	−10 p. c.	Some drying.
Croydon	*	−17 p. c.	?	Much drying.
Cardiff	34½	−17 p. c.	?	Much drying.
Merthyr	38½	−11 p. c.	−12 p. c.	Some recent drying.
Stratford	26⅜	− 1 p. c.	− 4 p. c.	Some local drying.
Penzance	30½	− 5 p. c.	0	No change.
Brynmawr	28½	+ 6 p. c.	− 8 p. c.	No notable change.
Morpeth	30½	− 8 p. c.	+12 p. c.	No change.
Chelmsford	32½	0	+11 p. c.	Slight drying.
Penrith	39½	− 5 p. c.	+27 p. c.	No change.
Ashby	25½	+19 p. c.	−10 p. c.	Some drying.
Carlisle	32	+10 p. c.	+11 p. c.	Drying (with local defects).
Alnwick	28⅜	+20 p. c.	+36 p. c.	No drying.

It is perhaps worth while to give some details as to one or two of these towns, since the full significance of the change that has been effected in them by drainage works can hardly be appreciated otherwise.

In 1851 Mr Rammell had reported of Salisbury as follows: "Numerous streams of water, supplied by the Avon, run through most of the streets. . . The soil is a porous gravel, containing everywhere a great deal of water, which rises to within a short distance of the surface. There have been several instances of the cathedral being flooded by the water of the subsoil. The foundations of the houses are almost without exception damp." The water supply is from wells "dug about eight or ten feet deep, the water rising to within three or four feet of the surface." Mr Middleton had drawn public attention to the same point in his address to the British Association in 1864. Apart from the bad system of drainage which the canals of Salisbury were made to serve, he clearly showed that they were also injurious by keeping the subsoil constantly damp.† In 1853 efficient drainage works were begun in Salisbury, and they were completed in 1855. In 1865 Dr Buchanan writes as follows: "The subsoil is now dry, and cellars of considerable depth can now be made in different parts of the town which do not become flooded at any time. On an average the sub-

* "Phthisis and other lung-diseases" together were previously 59½ p. c. Reduction of this rate is what is above given for Croydon. (Ninth Report, 1866, p. 48.)

† "Benefits of Sanitary Reform at Salisbury," 1865.

soil water has been lowered four or five feet all over the city. The cathedral has never been flooded since the drainage works. As is shown in the table, the annual death-rate from phthisis fell in Salisbury from 44⅓ per 10,000 in 1844–52, to 22⅔ per 10,000 in 1857–64."

Of another town, Banbury, Mr Rammell had reported in 1850 in the following terms :—"The drains are not all at a sufficient depth to drain the cellars of the houses. In the principal streets of the town water is raised from the cellars into the drain by buckets, and creates a nuisance." Sanitary operations were begun there in 1854. "At present," says Dr Buchanan, writing in 1865, "the sewers and drains all act efficiently. . . . Many of the wells of the town have been dried by the sewers." As appears from the table, the phthisis death-rate for 10,000 has declined from 26⅔ in 1845–53 to 15⅝ in 1857–64.

It must of course be understood that drying of the subsoil is not the only improvement that has been made in these towns. Excreta have at the same time been carried off from the houses, a good water supply has often been provided, and overcrowding has been diminished. Now, as regards removal of filth it does not seem that this has acted in reducing the death-rate from phthisis. Dr Buchanan placed the several towns in another list, according to amount of decrease in the mortality from enteric fever, and the order in which they stand in the phthisis-list is by no means the same as that in the fever-list, which appears to be more affected by removal of filth than by anything else. Many of the towns lower down the phthisis-list, such as Alnwick and Brynmawr, had made very good arrangements for carrying away excreta. And, on the other hand, Worthing and Rugby, both of which stand well in the phthisis-list, are very low in the fever-list. The cases in which "sanitary works" have failed to reduce the death-rate from consumption are chiefly those in which the soil previously contained little water (as at Penzance and Brynmawr), and those in which the deep drainage was effected by impervious pipes laid down in compact channels (as at Penrith and Alnwick) so that no extensive soil-drainage could occur either through or beside them.

The importance of these observations appeared to be so great that, in 1867, Dr Buchanan was directed by the Privy Council to make a special investigation in the three south-eastern counties, Surrey, Kent, and Sussex, for the purpose of determining whether any relation could be traced between the prevalence of consumption and the state of the soil as regards moisture. These three counties were chosen because in them only had the Geological Survey then minutely mapped out the surface ; but no part of England could have been better adapted to the purpose, on account of the great varieties of soil found there and the comparative absence of other differences between the several districts.

The first point was to ascertain the extent to which phthisis prevailed in different parts of the three counties. The basis for this part of the inquiry was afforded by the Registrar-General's Returns. Of course they cannot pretend to exact pathological accuracy. But seeing that in each registration district the certificates are furnished by several medical men, it is not likely that any serious error can result from their being used for the purpose of comparing the death-rate from so common a disease as consumption in one district with that in another. Moreover, if cases of phthisis are wrongly returned under any other head, it must be generally under that of bronchitis or of some other lung disease. Dr Buchanan, therefore, took pains to con-

sider the mortality from lung diseases in general, as well as that from phthisis, before he drew his conclusions.

Corrections had to be made in the returns for certain districts on account of the presence of camps or dockyards, causing the population to have a large excess of men in the prime of life; in others the returns were vitiated by their containing hospitals or asylums; in others, again, by their being resorts for invalid visitors; eight districts were set aside as being subject to one or other disturbing influence, which rendered their true consumptive death-rate uncertain. There were left fifty other districts which it was believed could be fairly compared with one another.

In instituting this comparison, Dr Buchanan first classified the several districts as having mainly soils *permeable* by moisture, or soils of such a character that water is unable to escape from them, so that they might be called *retentive*. He then massed together the fifty districts into five groups of ten each, according to the greater or less prevalence of phthisis in them, and in this way he obtained the following table.

Groups of districts.	Proportion of population (per 1000) residing on	
	Permeable soils.	Retentive soils.
A. With least phthisis	909	91
B. With next least phthisis . . .	877	123
C. Middle as to phthisis . . .	795	205
D. With more phthisis	792	208
E. With most phthisis	642	358

He pointed out that this tabulation, apart from arithmetical objections, must be corrected by certain geological considerations. Where the soil is pervious, its being moist or dry must depend entirely upon whether the water which reaches and sinks into it can escape through or from beneath it. It is no advantage for a place to be situated on gravel if the subsoil water cannot get away. Roughly, one may say that such a district will be *dry* in proportion as it *lies high* in relation to the places round it, *damp* in proportion as it *lies low*. On the other hand, among impervious soils, the question of dryness or moisture is almost entirely one of the *inclination of the surface*. Even among clays there is a great difference as regards dampness, according to the flat or sloping character of the ground.

A more exact comparison between retentive and pervious soils in regard to the prevalence of phthisis is afforded by a limited area, the Wealden, which in part is formed by the Weald clay, in part by the Hastings beds of alternate sands and clays. There are, indeed, no districts wholly of sand to contrast with others wholly of clay; but there are great differences in the proportion of the two soils in different districts. How closely these differences correspond with differences in the consumptive death-rate appears from the table on the opposite page.

The districts are arranged in order of the death-rate from phthisis, those being placed highest in which it is least. Where there are gravels over the Weald clay the figure is divided between the last two columns, it being presumed that they occupy an intermediate position.

Still more striking perhaps are certain comparisons between particular sets of districts which differ—if *pervious*, in being *high-lying* or *low-lying* respectively; if impervious, in being *sloping* or *flat*.

District (in order of phthisis death-rate).	Percentage of population resident on						Total on	
	Higher beds, mostly Lower Greensand.		Weald clays.		Hastings beds.		Sands + half gravels over Weald clay.	Clays + half gravels over Weald clay.
	Sands.	Clays.	With gravel.	Without gravel.	Sands.	Clays.

(1) As between *high-lying* and *low-lying pervious* soils, a contrast is afforded by districts formed by the chalk. No soil is drier than chalk when it has a good elevation; at its higher parts there are no streams, water cannot be reached by ordinary wells, and the people can only obtain a water supply from less elevated ground. In many districts, however, the bulk of the population who live on chalk occupy valleys with the water-line in the chalk not very far below their houses; and in the south of Sussex a still greater degree of wetness is reached, for a large part of this area reckoned as chalk is a flat plain on the sea level, covered by gravel, with the dip of the chalk here and there inland. Accordingly, we find the phthisis death-rate for North Aylesford and Dover (both of which lie high) to be 289 and 296 respectively; while those for Worthing, Lewes, and Westbourne (all of which lie low) are 419, 426, and 498. In general, Dr Buchanan adds, the connection between a low death-rate from phthisis and elevation of the chalk area is unmistakable.

So, again, with regard to the population living mainly on the Lower Greensand, there is a great contrast between a southern tract of this formation which lies low and the hills which are made up of it elsewhere. And a corresponding difference exists between the phthisis death-rates of Thakeham, Midhurst, and West Ashford (454, 455, 421 respectively) and those of Reigate and Godstone (337 and 282).

(2) As between *sloping* and *flat impervious* soils, a capital contrast is presented by two widely distributed tracts of clay, the London clay and the Weald clay. The former in its main extent throughout the three counties is disposed in long slopes or hills; the latter constitutes sometimes gently undulating, but more often flat and level ground. The former is covered over large areas by gravel reaching to many feet in thickness; the latter has only very level gravels, occupying its undulations, and these are seldom thick. The former generally has the direction of drainage from other beds away from it; the latter is always bounded immediately to the north and to the south by higher grounds, so that other beds drain more or less into it.

All these considerations show that the London clay is commonly much less wet than the Weald clay. The difference between the two formations in respect of their phthisis death-rate is, Dr Buchanan says, unmistakable. All districts that have even a third of their population on Weald clay have a high mortality from consumption, whereas there may be in a district a notable proportion of uncovered London clay without any like result.*

ix. *Direct injury.*—Whether this can be enumerated among the causes of phthisis is very doubtful. In 1880 there died at Guy's Hospital a man, aged thirty-eight, a patient of Dr Moxon. He had been a cab-driver, but was said to have been very moderate in his habits; there was no history of consumption in his family. Four weeks before his admission his cab had been upset and turned over upon him. Afterwards he spat a little blood, and three days later he brought up half a pint of blood. Of course he regarded his illness as the direct result of the accident, but the physical signs were exactly like those of phthisis affecting the left lung. When he had been in the hospital two months and a half he died. The left lung was found to be destroyed by a phthisical affection of "pneumonic" character. The upper lobe and the upper part of the lower lobe were hollowed out into a number of cavities; the rest of the lower lobe was consolidated by a pinkish-grey infiltration, scattered in which were many yellow tubercles and caseating patches with sinuous edges. But the right lung was affected with a more chronic form of the disease; in the upper lobe was scattered much pigmented grey tubercle; there were also some caseous tubercles, and one or two small vomicæ. The tubercular nature of the disease was confirmed by the fact that the small intestine contained ulcers which showed yellow submucous tubercles in the floor. In the larynx, too, there was a deep ulcer over the left arytænoid cartilage. Evidently the accident can only have accelerated a morbid process already in existence.

In four other cases phthisis followed an accident; in one there was fracture of ribs, in another fracture of the collar-bone, in the other two injuries of an undetermined kind from a fall into the hold of a ship and from a railway accident respectively. But in none of these cases is there any proof that the lungs were previously healthy; nor, indeed, is it certain that there was any closer connection between the accidents and the pulmonary disease than mere coincidence (*cf. supra*, foot-note, p. 1068).

The analogy of some other tubercular affections, as those of the kidney and the joints, would lead one to admit that an injury to the chest might set

* See on this subject and the ætiology of phthisis generally the valuable Milroy Lectures before the College of Physicians by Dr Ransome, of Manchester, in March, 1890.

It is right to mention that Dr Kelly, the Medical Officer of Health for East Sussex, has expressed doubts of there being any intimate relation between dampness of the soil and phthisis. He finds that in the years 1861–70 the order in which the several districts have to be placed in regard to their death-rates from phthisis is different from that given by Dr Buchanan for 1851–60. He points out that most of the impervious beds are to the north of the South Downs, and that consumption seems most common in places which are bleak and exposed as well as damp. He insists on the fact that in West Sussex (as indeed throughout England and Wales) there has of late years been a great decrease in the mortality from consumption, although there has been no change in the drainage of Sussex. Dr Kelly is inclined to attribute it mainly to the progress which has taken place in the social state of the rural population. Hirsch doubts the direct effect of good draining, and quotes the experience of Berlin, Dantzig, and Brunswick, of improved drainage being followed by increased death-rate from phthisis.

It is much to be desired that by a Royal Commission, or any better means, an extensive and searching official investigation over long periods of time should be undertaken, which might at least settle the facts upon which must rest the significance of damp soil and its share in the ætiology of phthisis.

up phthisis. But analogy is an uncertain guide, and considering how common are injuries to the chest, and how common a disease is phthisis, instances of a connection between them ought to be more frequent if it existed.

Opposing pathological conditions.—To complete our survey of the ætiological relations of phthisis, it is necessary that brief allusion should be made to certain conditions which have been, or still are, supposed to be *antagonistic* to its development.

One of these is habitual exposure to *malaria*. This opinion is now generally discredited in England, but Walshe brings considerable evidence in its favour.

The simultaneous occurrence of *carcinoma* and of tuberculosis is rare, but probably only due to the facts that each of these diseases is usually fatal, and that one of them chiefly attacks older, the other younger persons. Nine or ten cases occurred at Guy's Hospital between 1855 and 1874 in which more or less active phthisis had been present in patients who had also had cancer of the stomach, or womb, or œsophagus, or some other organ. One was a woman aged twenty-two, another a man aged twenty-four, a third a man aged thirty; the rest were older, and one had reached sixty-seven.

Antagonism between phthisis and *gout* has also been generally accepted, and probably not without reason. Both diseases are common in men between twenty-five and forty-five, yet cases of their concurrence in the same patient are rare. It would be interesting to know how often deposits of lithate of soda in the great toe joint are found in bodies which also show evidence of obsolete or recent disease of the apices of the lungs. That gout and active phthisis may coexist is proved by three cases observed during life and recorded in the 'Guy's Hospital Reports' for 1873 (vol. xix, p. 338), while in a fourth patient with gouty deposits in the joints signs of old phthisis and some recent clusters of tubercles were discovered in both lungs.

On the other hand, it appears to be indisputable that at least one kind of valvular *disease of the heart* is an almost complete bar to the development of phthisis. Mitral stenosis is exceedingly common in young persons, and it often fails for several years to affect the general health to any marked extent. That this lesion should be scarcely ever found in those who die of consumption is therefore a remarkable fact. Traube could not remember to have met with an instance. In our records of *post-mortem* examinations at Guy's Hospital, from 1854 onwards, only four examples occur. One was in a man, aged forty-two, whose mitral orifice was so narrowed, as the result of rheumatism, that it would only admit two fingers.* Traube speaks of having seen several cases in which persons with regurgitant disease of the aortic valves became affected with phthisis.

Whatever may be the explanation of the rarity of consumption in cases of mitral stenosis, it can hardly depend upon the venosity of the blood, as Rokitansky thought. For it is now well known that those who have congenital narrowing of the right sigmoid orifice are very apt to die of tubercular disease of the lungs. Traube says that he has seen two examples of this; and two occurred in the author's practice at Guy's Hospital.

Traube's view was that mitral stenosis, by causing serum to exude into the pulmonary tissue, prevents the occurrence of caseation; and Dr Hamilton, in the 'Practitioner' for 1880, throws out a similar suggestion.

* One of Dr Moxon's beautiful drawings in our pathological theatre shows how ill tubercular inflammation of the lungs thrives in cases of mitral disease.

It has been generally believed that pulmonary *emphysema* is unfavourable to the development of tubercle, and there is reason to believe that this is the fact. Even when emphysema supervenes upon primary phthisis the latter disease seems to be checked in the part so affected.

The supposed immunity of humpbacks from phthisis is not borne out by observation. Angular curvature of the spine usually depends on tubercular caries of the vertebræ, and is frequently followed by tubercular disease of the lungs (see a paper by the author in the 'Guy's Reports' for 1874).

Age and sex.—Phthisis may occur at all periods of life. The idea that it is a disease confined to young adults is inaccurate. At Guy's Hospital there has been little if any diminution in the number of fatal cases for each quinquennial period up to the age of forty-five. Several cases have occurred in persons between sixty and seventy, and two at the age of seventy-two. Probably these patients had phthisis in youth. At Copenhagen the proportion of deaths from phthisis to those from other causes increases with advancing years, and the same statistical result is reported from Würzburg and other parts of Germany. Statistics of Dr C. J. B. Williams's patients appear to show that, other things being equal, the *duration* of phthisis increases with age, and it is a matter of general observation that the disease in children runs an acute course, while senile phthisis is usually chronic. This would bring the average age at which it begins earlier than the statement of ages at death would indicate.

The period at which appeared the first decided symptoms of what afterwards developed into phthisis was found by Dr Williams to be distributed as follows among 1000 private patients:—195 cases at an age below twenty (of these only 13 under ten), 667 between twenty and forty (and of these 418 below thirty), 94 between forty and fifty, 30 between fifty and sixty, and in 14 cases symptoms only began at an age above sixty. The average period was later in men than in women.

More men than women die of consumption in the hospitals of London, although the Registrar-General puts the rates of males to females in the population generally as 3·77 to 4·13. Of Dr Williams's 1000 cases 625 were males and 375 females. Among the out-patients at the Brompton Hospital, Dr Pollock found 60·7 per cent. male and 39·3 per cent. female.

It must not be assumed that sex or age constitutes a predisposing cause of the disease in a strict sense of that term. The question may be of the more frequent operation, at different periods of life and in one sex rather than the other, of the various causes that have already been enumerated, particularly exposure and catarrh.

In women consumption shows itself, as a rule, earlier than in men, and more frequently runs a rapid course.

Geographical distribution.—Phthisis is, on the whole, more prevalent in temperate regions than in those which are very hot or very cold. It is endemic throughout Europe, and is most abundant in *large cities*, particularly in Paris and Vienna; but also in New York and Philadelphia, in Alexandria, and in Melbourne. It is probably as common in the United States, in China, and in Australia as in England; but is less so in the East Indies and within the tropics generally, although imported cases from Europe are said to be very unfavourably influenced by a hot climate. It is extremely rare in Iceland, in the highlands of the Andes, in New Zealand

and in some oceanic islands, in Syria, and in Upper Egypt. It is rare in swampy and malarious regions, as was first pointed out in 1812 by Dr Wells (the author of the essay on 'Dew'), and since confirmed by Boudin and many other observers. No quarter of the globe and no race of men is known to be completely exempt from consumption.*

Phthisis is well known among the lower animals, particularly the Quadrumana and the Ruminants (see, however, Mr J. B. Sutton's records, 'Path. Trans.,' vol. xxxvi, p. 546, and Dr Creighton's monograph on 'Bovine Tuberculosis in Man').

Prophylaxis.—It is doubtful how far it is possible to guard directly against the invasion of bacilli. Suspected milk may be boiled, crowded rooms may be ventilated, and the sputa of phthisical patients may be disinfected, but at present there is want of proof that "consumption hospitals" are dangerous, or that the health resorts for "poitrinaires" like San Remo and Davos, are more unhealthy than other places. Further investigation may show that though "infective" phthisis is not "contagious" (*i. e.* easily caught) except under special circumstances—as, for example, is the case with two well-known infectious diseases, syphilis and enteric fever.

The hereditary transmission of consumption is not altogether beyond the scope of prophylaxis. The physician's advice and the enlightened general opinion which he in time can produce may do much to prevent the intermarriage of cousins belonging to a phthisical family, and to dissuade from marriage those in whom symptoms of the disease have already appeared.

If a mother is known to be already phthisical, or even disposed thereto, it is a grave question whether she should be allowed to suckle the children.

Care should be taken that the residence of those who have tubercular tendencies should be on a dry soil. The rooms in which they live or sleep or work should be airy, well ventilated, and so situated as to be exposed to sunlight. Their food should be nutritious and fattening; and in feeding children it would probably be desirable to have all the milk boiled. They should have plenty of exercise in the open air, and they should be accustomed to exposure to the weather, but within reasonable limits. Cold bathing is advisable, provided that there is always a good reaction after the bath.

Special care should be taken during convalescence from whooping-cough and measles; and the recurrence of attacks of bronchial catarrh should be sedulously avoided. The habit of breathing with the mouth shut is an effectual preservative from most of the chances of catarrh, and possibly may make bacillary infection more difficult. Study, whether in preparing for examinations or in the pursuit of professional eminence, should be kept within bounds. Indeed, as adult life is approached, the necessity for moderation in all things should be impressed on everyone who would avoid the risk of phthisis. Temptations to intemperance and to dissipation must be resisted; but often the tendency of those who have a phthisical predisposition is rather to asceticism than self-indulgence, and this may be scarcely less physically harmful.

The son of a phthisical miner, or potter, or weaver should avoid such kinds of work, and country life should be preferred to the close and sedentary life of towns.

* See the diagrams in Dr Ransome's second lecture ('Brit. Med. Journ.,' March 8, 1890).

The diminution of the mortality from phthisis which has been observed in England (from 2567 per million in 1858–60 to 1541 per million in 1888), and also in New England (from nearly 4 pro mille in 1857 to about 3 pro mille in 1883), depends probably upon better drainage and better lodging; and, if so, is a great encouragement to prophylaxis in these directions.

Treatment.—This naturally falls under three heads:

(1) We must seek to check the early symptoms of phthisis, and to bring the disease to a state of obsolescence.

(2) A strenuous effort must, if possible, be made to arrest further progress or to prevent a relapse.

(3) If this fails, we must aim at retarding the fatal issue to the farthest attainable limit, and at relieving the most distressing symptoms.

(1) When phthisis sets in with inflammatory symptoms, with or without hæmoptysis, the patient should be put to bed and kept absolutely at rest. He should be limited for a time to a very light diet, consisting mainly of milk, without wine or other stimulant. Whether hæmorrhage has occurred or not, a very good prescription, if there is much pyrexia, is Niemeyer's pill of quinine (gr. j), digitalis (gr. ½), and opium (gr. ¼), to be taken every four or six hours. Tincture of iodine should be applied to the affected part of the chest, or even a blister, or the croton-oil liniment. It is almost an advantage to the patient, if he is to have phthisis at all, for it to set in with hæmoptysis; because then the real gravity of his condition is appreciated, and there is no hesitation in carrying out the measures which are necessary. "Catarrhal phthisis," in which one apex becomes quickly consolidated, has been held distinct from the "tubercular" form of the disease, because it yields so readily to treatment; and probably cases in which rapid consolidation occurs may run a more favourable course than others; but this may be because they are taken in hand more carefully and more energetically.

When the acute symptoms have passed off, the patient may go to the sea-side for a few weeks, or to some dry and healthy place inland, such as Tunbridge Wells or Malvern, or Ben Rhydding if the season be suitable. On the Continent a favourite plan is to send him to Lippspringe, near Paderborn, to drink the water of the lime spring there, or to Soden and other health resorts in the Taunus.

Sending a youth brought up in town to live in the country for several months, with strict attention to early hours, nourishing diet, and sedulous avoidance of all that is exciting, enervating, and exhausting, has often saved him from threatened consumption.

(2) It is impossible to insist too strongly on the importance of not letting slip the opportunity, which occurs in phthisis only at an early stage, of arresting its further progress, and of preventing a relapse. The measures by which this—the virtual *cure* of the disease—can be effected, involve, as a rule, a prolonged change of climate.

A long sea voyage, either to the Cape of Good Hope (or the highlands of Natal), or else to Australia by the Cape, or round the world. About twenty-three days are taken in going to the Cape, twenty-eight days to Natal; the voyage to Australia made in a steamer is about forty days, in a sailing ship, about three months. With regard to details, a knowledge of which is absolutely necessary to the invalid for whom a long voyage is recommended, information must be sought either in a little book by Dr Wilson, 'The Ocean as a Health Resort,' or in a series of papers by

Dr Faber, published in the 'Practitioner' during 1876–7. Sailing ships are preferable to steamers, one advantage being the greater length of the voyage, which renders the changes of climate less sudden and trying; while the greater cleanliness and quiet, together with the easier motion, are also strong recommendations. But, unfortunately, suitable sailing vessels are now seldom to be found. There is of course considerable heat in crossing the equator, and, on the other hand, during the latter half of the journey to Australia the weather is often cold and stormy. As large a part of the day as possible should be passed in the open air, and exercise on deck should be systematically taken. It seems to be important that the excessive appetite which generally arises should not be too freely indulged. A stay in Australia of from six weeks to three months should be made, at the end of which time the voyage home should, if possible, be made by the Cape, this taking generally three and a half or even four months. Dr Faber insists that no patient should be sent to the Antipodes who is not quite free from pyrexia in the evening; the climate of the tropics is very apt to cause increase of fever, and to render it continuous instead of hectic. It is also apt to bring on hæmorrhage, so that a marked disposition to hæmoptysis, or the presence of degenerated arteries are strong objections to a long sea voyage. The extent to which a patient is likely to suffer from sea-sickness cannot be foretold unless it has been proved by former experience; the result of a short trip across the Channel decides nothing.

Residence in an elevated mountain region, or at least in a dry bracing climate. It is impossible in the limits of this work to enter into details with regard to the climatic treatment of phthisis. The reader must consult the fourth edition of Dr Walshe's 'Diseases of the Lungs,' Dr Weber's translation of Braun's 'Baths and Waters,' and a little book by Mr R. H. Otter, entitled 'Winters Abroad;' also 'The Influence of Climate in the Prevention and Treatment of Pulmonary Consumption,' by Dr Theodore Williams; and Dr Weber's interesting Croonian Lectures on "The Hygienic and Climatic Treatment of Consumption," 'Lancet,' March, 1885.

Within the last few years it has become a common practice to send consumptive patients during the winter to Davos, a village situated in the Grisons, at an elevation of about 5200 feet above the sea. Other places, perhaps, might be found equally favourable; and St Moritz and Samaden, in the Engadine, had in fact been tried before Davos Platz, at least by English invalids. The Maloja Pass has more recently come into favour. The great peculiarity of the weather in these elevated stations is the stillness and the dryness of the air. In the shade the cold is extreme, but as the sun is very powerful, and as the sky is generally perfectly clear, patients are able to take exercise nearly every day—walking, skating, sledging, or "tobogganing." When sitting in the verandahs of the hotels the sunshine is hot. At night the double windows in the bedrooms are left slightly open; yet so motionless is the air that the temperature within scarcely falls below 50° Fahr., even when it is from 2° to 16° Fahr. outside. Many persons who are very liable to take cold elsewhere are free from the tendency at Davos. The proper time for a patient to arrive there is about the first or second week in October, or even earlier. It is generally supposed to be undesirable for him to remain after the beginning of April, when the snow melts. Unfortunately there is no little difficulty in saying where he should then go. He should on no account return to England before the first week in June; and during the interval the choice seems to lie between

Baden-Baden, Wiesbaden, Montreux on the Lake of Geneva, and Monte Generoso above Lago Lugano. The fact that hæmoptysis has been one of the symptoms does not appear to forbid sending a consumptive patient to Davos; but the actual presence of pyrexia is an objection, and still more so irritability of the larynx or trachea.

In America there are mountain climates in which phthisical patients derive great benefit without being exposed to extreme cold. This fact was pointed out long ago by Dr Archibald Smith, who practised for many years in Peru; indeed it seems to have been familiar to the Peruvians themselves, who regard the valleys of the Andes, from 8000 to 10,000 feet above the sea level, as almost omnipotent in the prevention and cure of consumption. As a general rule, it may be said that the nearer the equator the greater the elevation which is necessary to render a mountain region salutary in such cases. The chief resorts in the Cordilleras appear to be Huanuco and Jauja. Dr Walshe recommends, as more accessible, the plateau of Santa Fé de Bogotà in New Granada. A great peculiarity of this place is the equality of its climate at different seasons; the mean temperature of each quarter of the year is within a degree or two of 86° Fahr.

Other mountain regions to which phthisical patients may be sent are the table-lands of California and Mexico, Colorado,* Denver or Kansas City in the States, or Manitoba in Canada. One can hardly doubt that in the Himalayas also there must be valuable resorts; Dr Weber is inclined to think that the present military sanitaria there may not be at a sufficient elevation for the climate. The writer has seen excellent results from a whole phthisical family going to settle in Colorado.

A prolonged stay in the Southern Hemisphere during what would be the winter of Europe, but is of course summer there. Certain parts of Australia are very serviceable to phthisical patients. It must not, however, be imagined that a residence in the large towns is advisable. Melbourne, in particular, is apt to be intensely hot and dusty, with very rapid changes of temperature and cold winds; and Sydney and Brisbane are very hot. The best health resorts appear to be certain places in the interior of New South Wales, especially Bathurst, Goulburn, Boural (3000 feet above the sea), and Currajong, but, above all, the Darling Downs, in the south of Queensland, where the weather is cool, dry, and bracing. Tasmania and certain parts of New Zealand are suitable for consumptive cases; Hobart Town and Wellington or Auckland especially are well spoken of.

Certain parts of South Africa have climates which appear to be very favourable to phthisical patients, but no long stay should be made at the sea-coast; Mr Otter says not within 100 miles of it, nor at a less elevation than 1500 feet. The easiest way of reaching the interior is to land at Port Elizabeth, and to go on by Grahamstown to Cradock or to Bloemfontein, the capital of the Orange Free State. The difficulties are the badness of the roads, and the roughness of the accommodation. Bloemfontein has an exceedingly dry climate; the daily range of temperature is great, but this is said not to act prejudicially.

The working of change of climate, as a curative agent in phthisis, is still uncertain. In many instances the beneficial influence on patients who come from a distance finds its parallel in the fact that natives of the same district are very seldom, if ever, attacked. This appears to be the case, for

* See a paper on the "Climatic Treatment of Phthisis in Colorado," by Dr Charteris, of Glasgow ('Lancet,' November 26th, 1887).

example, in the high Alps, as well as in the valleys of the Andes, and until recently it was so in Australia, although the disease is now rife among the inhabitants of Melbourne and of other large towns there. But Dr Walshe and others have rightly insisted that there is no necessary connection between the two things, and there is no difficulty in finding countries, such as Iceland, to which one would not think of sending a consumptive patient, notwithstanding that the natives escape the disease. To the author it appears evident that the "aseptic" character of the air of a place cannot be the direct reason why phthisis should cease to advance in those who inhale it. Observations showing that meat remains fresh there longer than elsewhere are altogether inapplicable; the only case in point would be for putrefaction once started to be stopt. On the whole, it seems likely that the good effects of change of climate depend partly upon its improving the general health and increasing the resistance of the organism to the further progress of the disease, partly upon its protecting the patient from fresh attacks of bronchial catarrh. The number of bacilli found in the sputum is not diminished in Davos, according to Dr Theodore Williams.

(3) When the complete arrest of phthisis is no longer probable, much may still be done to prolong the patient's life and to give him relief from suffering. The climates which Dr Walshe terms *sedative* seem to have their chief use under such circumstances; for example, Madeira, and the Grand Canary, Pau, San Remo and some other places on the Riviera, Torquay, and Penzance. The climates which he classifies as *stimulant* include St Leonards and Hastings, various towns on the Riviera, Algiers, and even Egypt. Of Nubia he speaks in terms of the highest praise; and probably a voyage up the Nile is the best thing for patients who dislike cold, and who habitually feel better the hotter they are. That special benefit follows from the air having resinous smells from pine forests—as at Arcachon and Bournemouth—is easier to assume than to explain or to prove.

It must of course be remembered that phthisis sometimes becomes quiescent without any change of climate whatever. On the other hand, although it is a heavy responsibility to advise or allow a patient with confirmed phthisis to take a long sea voyage, or to spend a winter in Australia, in South Africa, among the Andes, or even at Davos, there is no question that, if he chooses to run the risks inseparable from such undertakings, he has at least a chance of unexpected benefit.

(4) In the last stages of phthisis, when palliation of symptoms is all that can be hoped for, we have practically to deal with cough, hectic fever, and diarrhœa, and with the other less constant or serious complications. At this stage it is most undesirable to send a patient away from the comforts of home. Opium, in one form or another is now the most valuable of drugs, and its effects are among the most striking instances of the power of the judicious practice of our art to alleviate and to soothe when it can no longer cure.

Physic and Diet.—The following is the list of drugs, regarded by Louis as important fifty years ago:—Steel, digitalis, common salt, carbonate of potash, chloride of ammonium, chloride of lime, hydrocyanic acid, creasote, and iodine. The inhalation of diluted chlorine gas, also, was fully considered and tried in fifty cases of phthisis in the Paris hospitals, and in no instance was there a successful result. Most of the other "remedies" are deservedly forgotten.

Quinine to give appetite or to moderate fever, preparations of iron for anæmia, digitalis to improve the pulse, sedatives to relieve cough or vomit-

ing, and laxatives and stomachics to help the appetite and digestion—these are rational and useful means of treatment; but chlorine has been followed into obscurity by the hypophosphites, by inhalation of carbonic acid gas,* and by inflating the patient's bowels with sulphuretted hydrogen.

Only one medicine has borne the test of long and wide experience, and this is not a specific remedy, but a kind of food, which has remarkable power of fattening the patient. *Cod-liver oil* was introduced for cases of chronic "rheumatism," but was first advocated as peculiarly useful in consumption by the late Dr Hughes Bennett. Now that it is taken by almost all consumptive patients, one is apt to underrate its real importance as a means of preventing emaciation and keeping up the strength. It is said to be less useful in proportion as the age of the individual is more advanced. It is best given after food, in doses of from a drachm to half an ounce two or three times a day. If it gives rise to nausea and vomiting, cream may sometimes be substituted for it, or glycerine, but they are not as good. With perseverance *small* doses of cod-liver oil can almost always be taken, at least during cold weather. It may be taken alone, or in orange or ginger wine, or as an emulsion. Chewing a bit of orange-peel is the best way to prevent the after-taste. In children cod-liver oil is often rubbed into the skin, but the smell is extremely unpleasant, and probably olive oil is just as good.

The first object in the early stages of phthisis, or of threatened phthisis which has not yet begun, is to improve the patient's *appetite and digestion*. This is one object of change of climate. If he gains weight he generally is doing well. Usually small doses of alkalies, with the milder and less astringent bitters and gentle laxatives, act best in this direction. The combination of carbonate of soda with rhubarb and calumba, long famous at Victoria Park and other hospitals, is excellent for the purpose. In the later stages laxatives must be administered with great caution, for nothing is then more injurious than diarrhœa. Sometimes strychnia and gentian or chiretta are borne well and help the appetite.

Fatty food, such as bacon, milk, butter, cream, dripping, is indicated. Wine with meals is as a rule desirable; but in early cases, before there is much cough, malt liquors, and particularly porter, are more useful. Brandy is, as a rule, best adapted for advanced cases, and even then should be given in moderate doses; but rum and milk, either before breakfast or between breakfast and lunch, is a well-known and useful way of giving a nourishing stimulant.

Treatment of special symptoms.—When severe *hæmoptysis* appears, the patient must be kept strictly in the recumbent position for two or three weeks at least. He should not be allowed to talk. His diet should be limited almost entirely to milk. He should have ice to suck, and everything that is given to him should be cold. Of styptics it is difficult to say which is the best; ergot, gallic acid, acetate of lead, opium, have each their advocates, and it sometimes seems necessary to try one after another. A large ice-bag may also be placed over the chest. When the hæmorrhage has ceased, the patient is very cautiously allowed to get up and to move about, and the amount of food is gradually increased, while the pulse and temperature are being carefully watched from day to day.

The *cough* of phthisis must be combated by the usual remedies. Most

* This remedy, recommended in 1795 by Dr Beddoes and James Watt the engineer, was once much employed, and has lately been revived.

prescriptions contain a small dose of opium or morphia, together with tolu, aniseed, benzoic acid, or some other of the so-called expectorants.

In most cases of phthisis there is early and marked *anæmia*, indicating the use of steel. This may be given as the sulphate, with small doses of Epsom salts, or in one of the milder preparations, or (if borne well) in the most efficient form, the muriated tincture, with glycerine and quassia or calumba. Arsenic may succeed when preparations of iron fail, and now and then has a remarkable effect in restoring appetite, and adding fulness as well as colour to the cheeks. Lately it has been given with salicylates.

Diarrhœa is often a most distressing complication, and does much to hasten the fatal termination. It is best treated by bismuth and soda, or by the aromatic chalk powder. Dover's powder is often useful, and occasionally, when the rectum is affected, a starch and opium enema or a compound lead suppository.

The only other symptom that needs special mention is the *night-sweating*. This may sometimes be checked by sponging the chest and the arms at bedtime with vinegar and water. Sometimes it ceases if a subcutaneous injection of atropine ($\frac{1}{200}$ to $\frac{1}{100}$ of a grain) is given at bedtime, or a dose of belladonna, oxide or sulphate of zinc, gallic acid, or strychnia. But in too many cases it persists in spite of all treatment.

Direct pulmonary applications.—Treatment by inhalation of compressed air,* of oxygen, or of other gases, is either useless or of very limited benefit. A mode of treatment, lately introduced by Dr Bergeon, of Lyons, gaseous enemata of sulphuretted hydrogen, has no theoretical probability to recommend it; it is unpleasant in its action, and after being tried (perhaps with more patience than was due to it) has been shown to be useless.

Of late, however, those who believe that the bacilli of tubercle are the efficient cause of phthisis have naturally attempted to destroy them by antiseptic methods. Iodoform and thymol have been given by the mouth with this object, and more recently sodic sulpho-carbolate and phenyl-propionic acid. Creasote, thymol, and eucalyptol have been inhaled by means of ori-nasal respirators (of which Sir William Roberts, Dr Burney Yeo, and others have devised ingenious forms); steam inhalers have been supplied with such antiseptic agents as creasote or carbolic acid, and similar solutions have been administered by Siegel's spray apparatus. Sometimes apparent benefit to the local and general symptoms has resulted, and the number of bacilli in the sputum has diminished. But experiments in the laboratory show that Koch's bacilli are extremely difficult to kill, and survive prolonged immersion in germicide solutions. Iodine and corrosive sublimate seem to have the most power in destroying them. Perhaps the most ingenious method of "bacillicide" treatment is that introduced by Dr Cantani, of Naples, who introduces the common *Bacterium termo* of putrefaction into the lungs in a spray, with the hope of its destroying the specific bacillus. Unfortunately the latter is the more powerful of the two; and Dr Theodore Acland reported, after a visit to Naples, that the results of this treatment are negative.

The eminent pathologist who discovered the bacillus of tubercle has been long engaged in search after some remedy which may render the organism refractory to the growth of the parasite; and it is reported that definite results have already been obtained in Professor Koch's laboratory.

* See some recent lectures by Dr T. Williams ('Brit. Med. Journ.'), 1885, vol. i, p. 769.

MILIARY TUBERCULOSIS OF THE LUNGS.—Both from a clinical and from a pathological point of view it is desirable to treat apart from cases of ordinary phthisis—in which tubercles spread through the lung from the apex downwards and produce softening and excavation—those of miliary tuberculosis, in which each tubercle appears to be the result of the deposition in the pulmonary tissue of a particle of virus (probably a bacillus, or the spore of a bacillus) brought to the organ from elsewhere by the blood-current. The cases which most demand attention in this chapter are those in which the lungs, previously healthy or but slightly affected with phthisis, become suddenly the seat of such immense numbers of tubercles that acute symptoms arise and death by asphyxia follows.

It must, however, be remembered that other organs are almost always attacked at the same time. If tubercles appear in the membranes of the brain, they generally (but not invariably) give to the disease its main clinical features. If the peritoneum is much involved, the abdomen alone may appear to suffer. So that it is often almost an accident whether a case is regarded during life as one of tubercular meningitis, or tubercular peritonitis, or miliary tuberculosis of the lungs; while there are other cases which run their entire course without definite clinical localisation. Nor is the severity of the pulmonary symptoms always proportioned to the number of miliary tubercles in the lungs. In cases clinically classified as tubercular meningitis the lungs are often found as full of tubercles as the pia mater.

Anatomy.—With regard to the morbid anatomy of miliary tuberculosis of the lungs there is little, if anything, to add to what was stated in the chapter upon Tubercle in general. As was there remarked (p. 319), many cases occur in which the greater abundance and more advanced state of the tubercles in the upper lobes, than towards the bases, prove that the proclivities of the pulmonary tissue in different regions produce their effect on this disease as well as in phthisis. It has also been noticed that when a general outbreak of miliary tubercles occurs in a patient who previously had the apex of one lung affected with phthisis, the tubercles in that lung are more numerous (or perhaps larger) than in the opposite one. The characters of the tubercles themselves vary widely in different cases. Sometimes they are grey, and tend not to caseation, but to fibrous change or to horny induration (p. 307). Sometimes they become cheesy almost as soon as they are formed. In some exceptional instances, and only towards the apices, they are found to have already softened in their centres with minute vomicæ.

Physical signs.—These are in most cases vague and doubtful.

In all probability miliary tubercles are never set sufficiently close together, even in the apex of a lung, to impair the percussion-resonance of the corresponding part of the chest. Sometimes it appears doubtful whether the sound is not slightly dull beneath one or both of the clavicles; but if this is so, the dulness is most likely due, not to the tubercles themselves, but to the collapse of the surrounding pulmonary tissue. Dr Eustace Smith remarks that in children this interpretation is borne out by the fact that variations may be observed from day to day, the resonance becoming good where it had been deficient; and the case of an adult patient will be presently mentioned in which the same thing seemed to occur. Again, it is not uncommon for the presence of pulmonary emphysema to render the percussion-sound over-resonant; and the progressive emaciation of the patient makes the still spongy parts of the lung give a more resonant note.

In many cases any dulness under the clavicle is due not to the acute tuberculosis, but to the preceding chronic phthisis.*

With the stethoscope one may be able to detect absolutely nothing abnormal, even when tubercles exist in enormous numbers. But in some cases, especially towards the apex, the vesicular murmur has a harsh quality, the cause of which is not apparent. More frequently the auscultatory signs of bronchitis are present, sometimes to an extreme degree. Not only may sibilus and rhonchus be audible, but also abundant moist sounds. The expiration, too, may be prolonged and wheezing. In such cases the smaller tubes are found reddened and filled with muco-pus—clear proof of bronchitis. Sometimes the moist sounds are so bright and clear—so consonating in quality—over the upper lobes, that it is difficult to believe that there is not diffused infiltration, with "breaking up" of the pulmonary tissue. In one such case which occurred at Guy's Hospital in 1874 there were in fact a large number of small cavities, especially in the left apex. These were evidently of older date than the general eruption of miliary grey tubercles, which filled every organ in the body, and it appeared from the history that the patient had had a cough for three months, whereas his more acute illness began only ten days before death. But in another case, in 1868, it is reported that there were mucous râles at the left apex, gurgling at the left base, and "pneumonic crepitation" over the right upper lobe; and yet the tubercles were nowhere seen softening, the only source of the moist sounds being pus in the smaller tubes. In many instances the autopsy has shown that the lesions were much less advanced than had been thought during life. This occurred in a woman, aged twenty-five, in Guy's Hospital. When she was admitted on July 19th, 1882, the only physical sign was a slight crackling sound heard at the right apex after she coughed. However, on the 28th there was a marked crepitant râle in both upper lobes, and especially along the anterior edges of the lungs; and during the next three or four days its character became so "consonating" that we were almost disposed to look upon the disease as acute pneumonic phthisis rather than as miliary tuberculosis. But at the autopsy, made on August 4th, the lungs, though bulky and œdematous, everywhere contained air; the tubercles were discrete, and caseous only in the upper lobes; the tubes yielded a frothy fluid.

Clinical symptoms.—These fall under two heads: first, pulmonary symptoms; and secondly, pyrexia of a peculiar kind.

There is always more or less troublesome *cough*, generally short and hacking, and often dry.

The *sputum* when present often consists of clear mucus; occasionally it is muco-purulent. There are not infrequently streaks of blood in it, and

* Jürgensen described in the 'Berliner klin. Wochenschrift' for 1872 a case in which during five days he heard over a large part of both sides of the chest a peculiar soft, rubbing sound, perceptible also to the touch; when death occurred, two days later, the only cause to which this sound could be attributed was the presence of a number of miliary tubercles situated on the right side beneath the pulmonary pleura, which was free, and on the left side in the substance of adhesions which obliterated the pleural cavity. From the very first day the soft quality of the sound led him to conclude that it was produced by miliary tuberculosis, and not by pleurisy. The patient complained of no pain, and could draw a deep breath without embarrassment. Jürgensen thinks that in future cases a positive diagnosis may safely be based upon this sign. Burkart has since stated (in vol. xii of the 'Deutsches Archiv') that he has twice detected a rough friction-sound, due to the presence of obsolete tubercles.

still more rarely it may be "rusty," like the sputa of acute pneumonia, or even plum-coloured. Actual *hæmoptysis* in any considerable quantity is not common. But in 1869 there was brought into Guy's Hospital the dead body of a child, aged five, who was said to have been well on the previous evening, and to have eaten some herring for supper. In the course of the night it was found to have brought up blood, and to be in an alarming state, and it died on its way to the hospital. An autopsy showed that there was an acute general tuberculosis; and some of the tubercles in the lungs were already caseating, especially in the upper lobes. No definite source for the bleeding could be discovered; the pulmonary tissue was mottled with blood drawn into it by inhalation. In all probability the cause of hæmoptysis in such cases is the extremely congested state of the vessels immediately around the tubercles, which often gives them the appearance of being surrounded by a reddish-brown border after death; in fact, obvious points of capillary hæmorrhage may sometimes be seen, not only in the lungs, but in other organs.

Far more significant than cough or sputum is *dyspnœa*. At first the breathing is only hurried; the number of inspirations in the minute gradually increase up to fifty or sixty, and in children to eighty or ninety. In the woman aged twenty-five, whose case was mentioned above, it was counted at fifty-six on the very day of her admission. After a time the patient becomes conscious of shortness of breath; there is orthopnœa, the movements of the thoracic muscles are forced, and the nostrils work. The cheeks, the lips, the fingers, and the nails are of a purple colour. This cyanosis, perhaps more than any other symptom, suggests the idea of pulmonary tuberculosis, when there is no long-standing emphysema or heart disease to account for it. Very seldom is it stated to have been absent.

Sometimes albumen appears in the urine. There is not infrequently slight œdema of the lower limbs, and the face becomes puffy and swollen. In the case of the young woman already referred to, the urine contained sugar during the first few days after her admission into the hospital, the proportion being on one occasion 0·4 grain, and on another occasion 0·265 grain in the ounce. Senator's experiments seem to show that this cannot be attributed to deficiency of oxygen in the blood; and, indeed, as the case went on and marked cyanosis developed itself, the glycosuria ceased.

Pyrexia seems to be invariably present, but it varies greatly in its degree and in its course. Sometimes the temperature ranges up to 104° or 105°, but more often it remains at a lower level, perhaps not at any time exceeding 102°. Its progress is irregular. For two or three days there may be scarcely any differences in the thermometric readings at different periods of the twenty-four hours; and then the usual diurnal variations may appear in an exaggerated form, or what is termed the *typus inversus* may show itself, the morning temperature being higher than that of the evening. Brunniche is said to have observed this in fifteen cases out of seventeen.*

The onset of the pyrexia is usually gradual, and the patient does not take to his bed until he has been ailing for some days. But Rühle, in 'Ziemssen's Handbuch,' speaks of an initial rigor as not infrequent. There are the ordinary early febrile symptoms of headache, malaise, depression,

* Jürgensen makes it a point that the pyrexia does not yield to tepid baths or to antipyretic remedies so readily as in the specific fevers. This opinion, however, seems to have been partly theoretical, and based upon the idea that in tuberculosis the high temperature of the body generally is the result of the local morbid process, just as when there is inflam-

intense thirst, and loss of appetite. The skin is often wet with perspiration. Epistaxis occurs in some cases, and herpes may appear about the mouth.

The *pulse* is generally very rapid—often out of all proportion to the height of the temperature. There may be a flush on the cheeks, but the face is more usually pale before it becomes livid. At one time it was taught that in miliary tuberculosis enlargement of the spleen is exceptional. But all observers seem now to be agreed that some degree of swelling of the organ is usually to be detected by careful percussion. Rühle says that if tubercles are developed in the spleen it may be tender on pressure, and become as large as in enteric fever. This was the case in a patient under the writer's care in December, 1888.

Towards the end a typhoid state may develop itself, with sordes, a dry brown tongue, subsultus, delirium, and coma. Death is sometimes preceded by a rise of temperature, sometimes by a fall and by collapse.

Diagnosis.—One is often helped in the recognition of miliary tuberculosis of the lungs by indications of a like affection of some other organ. Thus the case may at any period of its course become complicated with symptoms of tubercular *meningitis* or *peritonitis*. Occasionally a tubercular *arthritis* may perhaps aid in clearing up the nature of the disease.* Cornil and Ranvier have shown that in cases of acute tuberculosis miliary granulations may often be found in the cancellous tissue of the bones, especially in the vertebræ, the sternum, and the ribs; and possibly their presence may sometimes give rise to pains vaguely referred to different parts of the limbs and body.

From a clinical point of view, the most important disease to distinguish from acute tuberculosis is enteric fever. Both diseases occur in patients of the same age, both are attended with pyrexia, both run an acute course, and in both the lungs are constantly, the intestines and peritoneum sometimes, the seat of disturbance. The temperature in tuberculosis is less regular, and interrupted by subnormal readings; the ratio of respiration to pulse and temperature is greater, and cyanosis comes on earlier. Moreover, some chronic disease of the pulmonary apices is often to be discovered. The rash and characteristic stools are absent, but both may be so in enteric fever.

Next to enterica we must remember the pyrexia of pyæmia, and particularly of internal pyæmia, such as from endocarditis or caries of the internal ear.

In the majority of cases of acute miliary tuberculosis of the lungs there are physical signs of previous phthisis, often of old standing or even appa-

mation. But since the discovery of the bacillus it is probable that the presence of this organism in the blood is the chief cause of the pyrexia; and, if so, the distinction from a specific fever can no longer be maintained.

* A striking example of this was recorded by Laveran in the 'Progrès Médical' for 1877. A man, aged twenty-two, was attacked with articular pains, especially in the knees. Effusion occurred into the right knee-joint, and when admitted into hospital he was supposed to be suffering from subacute rheumatism. However, at the end of a week great dyspnœa set in and high fever, the temperature ranging from 102° to 104°. A fortnight later he died, the cause of death being acute tuberculosis. The synovial membrane of the right knee was found to be injected and covered with a large number of greyish granulations the size of pins' heads, which could be felt. Where they had been in contact with a surface of articular cartilage their summits were flattened. A few granulations were present also in the left knee.

In 1867 a woman died in Guy's Hospital of tubercular meningitis, whose right knee had become swollen and painful in the course of her illness. At the autopsy all that was noted was that the synovial membrane was very vascular and œdematous, and that the cartilage over the external condyle of the femur was slightly eroded. But it is not at all unlikely that tubercles were present.

rently obsolete; or if these are masked by the more recent and acute malady, we have a history of cough, wasting, or hæmoptysis; or the clubbing of the fingers may point to long-standing deficient aëration of the blood. The prevalence of phthisis or other tubercular disease in the family is another point which often helps in deciding the diagnosis of an acute febrile attack.

Acute capillary bronchitis, when it occurs in a young adult, is sometimes most difficult to distinguish from miliary tuberculosis of the lungs; or, rather, it is difficult to decide whether capillary bronchitis is due to the presence of tubercles or is the only disease. In young adults the latter is improbable, but the writer had two cases during the winter of 1889–90, in a young man and a young woman, in both of whom there were no tubercles or other complication.

As a help to diagnosis, the most important seat of miliary tubercles is one where they can actually be seen during life.

In 1857 Manz discovered tubercles in the *choroid* of each eyeball in the body of a girl who had died of acute tuberculosis, and he and Busch afterwards recorded similar instances. In 1867–8 Cohnheim, investigating this point carefully in all the cases of miliary tuberculosis—eighteen in number—that came under his notice in the Pathological Institute at Berlin during a period of fourteen months, found that in every instance one or both of the eyes—almost invariably both of them—showed choroidal tubercles. In April, 1867, the ophthalmoscope was for the first time used, apparently by v. Graefe himself, for the discovery of these tubercles during life in a patient of Griesinger's. In November of the same year Mr Soelberg Wells exhibited to the Pathological Society of London a specimen of choroidal tuberculosis, which he had detected in a little girl under the care of Sir Alfred Garrod, five days before her death. Since then many other observers have recorded similar facts. But further experience seems to have shown that the eyeballs are far from being so constantly involved in cases of miliary tuberculosis as Cohnheim supposed.*

In acute cases the number and the size of the tubercles may increase from day to day, as was noticed in a child examined by Fränkel and by Leber. If, however, nothing should at first be detected by the ophthalmoscope in a suspected case of general miliary tuberculosis, the instrument ought to be used again and again as the disease advances. The tubercles vary much in size. The largest seen by Cohnheim was 2·5 mm. in diameter; but Ponfick met with one that measured 5 mm. On the other hand, Cohnheim seems often to have detected them (in the dead body) where they could only be seen after carefully removing the choroidal pigment, and even where they were too small to be visible by the naked eye. Perhaps this may account

* One of the most remarkable cases was recorded by Fränkel in 1872 in the 'Berliner klin. Wochenschrift.' A delicate girl of six was attacked in May of 1871 with slight shiverings, and her temperature rose occasionally to 100·4°. Then partial ptosis appeared, and afterwards paralysis of some of the ocular muscles. On May 22nd the ophthalmoscope showed a white patch to the upper and inner side of the disc in the left eye; it was as large as the disc itself, and had a rounded form, except that in one direction it was drawn out into a point. By the 1st of June it had increased in size by one half. On account of its characters being so different from those generally described as belonging to tubercles in the choroid, Fränkel hesitated to diagnose it as tubercular. The child now went into the country with her parents and remained there until August, when she came back apparently in perfect health. The patch in the fundus of the eyeball, however, was more prominent, though not larger than before. On August 21st she became ill with gastric symptoms and pyrexia, and died on October 1st. On September 10th five fresh miliary tubercles had been detected in the choroid. Vision remained unimpaired until death.

for the discrepancy between his statements and those of other observers as to their inconstancy in general tuberculosis. Where there are but few of them they seem to be developed in the neighbourhood of the disc or of the yellow spot more often than towards the equator of the eyeball. When very numerous, some of them may run together into irregular masses. They almost always become caseous as soon as they reach about 1 mm. in diameter. With regard to the ophthalmological diagnosis between tubercles and the white spots that are seen in disseminated choroiditis, von Graefe and Leber insisted on the rounded form generally presented by tubercles, their projecting above the level of the choroid, the gradual thinning away of the choroidal pigment from their periphery inwards to their centres, which appear white, and the absence of any accumulation of pigment outside them, except perhaps when they are very large. It is very rare for the sight to be affected.

Ætiology.—Pulmonary tuberculosis is seldom the result of caseating tubercular glands which had been recognisable during life. Many of those who are attacked, whether children or adults, are robust and healthy-looking. On the other hand, one must always be prepared for the supervention of miliary tuberculosis in cases of phthisis; for in the vast majority of cases acute miliary tuberculosis is secondary to chronic tubercular and caseous inflammation of the lungs or some other organ.

Acute tuberculosis occurs at all ages, but is most frequent in young adults. Burkart records the case of a woman, aged twenty-eight, who died after a fortnight's illness, and in whom the lungs, the peritoneum, and the kidneys showed recent miliary tubercles, while in the intestine there were the typical lesions of enteric fever. He also cites eight cases recorded by Birch-Hirschfeld, in which acute tuberculosis developed itself after enteric fever. In children the disease often follows measles, scarlet fever, and smallpox.

Among forty cases observed at Guy's Hospital between the years 1857 and 1873, one was in an infant aged nine months, three were in patients between one and ten years, seven between eleven and twenty, thirteen between twenty-one and thirty, six between thirty-one and forty, four between forty-one and fifty, six between fifty-one and sixty. This list does not include the cases in which the clinical symptoms were those of tubercular meningitis; if they were taken in, the proportion of children would be far higher. Burkart gives very similar figures. Among the above cases there were almost exactly twice as many males as females; among Burkart's the proportion was as sixteen to two.

Prognosis.—The duration of the disease is commonly three to four weeks, reckoning from the first commencement of marked symptoms up to the time of the patient's death; but there may be a protracted illness, lasting three or four, or even eight months. Clinically, acute pulmonary tuberculosis resembles severe bronchitis more than any other affection, and is not seldom mistaken for it until an autopsy reveals the real nature of the case. Indeed, as Burkart has remarked, it is common for miliary tuberculosis to develop itself in lungs which are already emphysematous from old bronchitis. Twelve of his eighteen cases were examples of this, and their course was often very prolonged. In no fewer than six of these, in fact, the tubercles were already calcified or fibrous, with a lustre like that of mother-of-pearl, so that they might fairly be considered obsolete; and the cause of death was sometimes pleural effusion, sometimes dilatation of the right side of the heart, sometimes Bright's disease; the presence of the

tubercles seemed to be little more than an accident. A similar obsolescence of pulmonary tubercles has been observed by the author.

This question of the possible involution of miliary tubercles in the lungs is of great importance. It has been usual to regard the fact that a patient recovers as conclusive proof that he was not suffering from miliary tuberculosis; although Dr Bristowe says that the progress of the disease "may be occasionally arrested, but with more or less permanent damage to the tissue of the lung." But, in cases of fatal tubercular meningitis, we often have opportunities of observing that the number of miliary tubercles scattered through the lungs may be very small. And it is difficult to say why, if the meningitis were absent, recovery should not take place.

Wunderlich, as far back as 1860, recorded in the 'Archiv für Heilkunde' cases which he regarded as examples of cured miliary tuberculosis; but he based his diagnosis solely on the fact that the temperature chart failed to correspond with what he regarded as a necessary course of enteric fever. Few observers will be found at the present time to endorse his opinions in this respect. Perhaps the only way in which the occurrence of recovery from an attack of miliary tuberculosis could be proved by clinical evidence alone would be by the discovery of tubercles in the choroid of the eye. Or the patient, after getting well, might die from some other cause, and the tubercles be found in a state of obsolescence. In regard to this, Dr Bristowe speaks of the lung, after the arrest of the discrete tubercles, as becoming "seamed throughout with minute patches of cicatricial tissue, the fibres of which have something of a stellate arrangement, and within the limits of which the lung-tissue presents, from the presence of concurrent emphysema, a coarsely spongy character; occasionally, in the centres of the scars, minute fibroid knots or concretions may be recognised."

With regard to the *treatment* of miliary tuberculosis of the lungs, all that can be said is that the strength of the patient should be maintained, that symptoms should be checked by appropriate drugs, and that perhaps bichloride of mercury or some other parasiticide should be given in the hope of favouring the obsolescence of the tubercles.

CATARRHAL DISORDERS OF THE AIR-PASSAGES, WHOOPING-COUGH AND ASTHMA

IN the present chapter will be described certain affections of the upper air-passages: catarrh and other affections of the nasal mucous membrane; and also whooping-cough and asthma, which are clinically related to bronchitis and dyspnœa, although pathologically the one might find a place among specific fevers, and the other among spasmodic disorders.

NASAL CATARRH.*—Almost everyone, at least in England, is liable from time to time to a "cold in the head." This affection commonly begins with sneezing, repeated again and again. The nose becomes dry and "stuffy," its mucous membrane may be seen to be swollen and injected, and there is difficulty in breathing through it, so that the mouth is kept open for breathing; and the nasal consonants *n*, *m*, and *ng* cannot be pronounced, but become *d*, *b*, and *g* respectively. Then follows a profuse flow of a thin, saltish, watery fluid from the nostrils, so that the handkerchief is continually in use. Smell and taste are completely abolished for the time. If the frontal sinuses are involved, there is dull pain in the forehead, or severe headache. Extension to the lachrymal passages causes the tears to flow over the cheeks, and the conjunctiva becomes injected. Extension from the fauces to the Eustachian tube may give rise to deafness. The skin near the nostrils often becomes inflamed and excoriated by the discharge.

* *Syn.*—Coryza, κόρυζα—Pituita capitis vel nasi—Gravedo—Catarrhus endemicus, Catarrhus a frigore.—*Anglice*, Cold in the head.—*Fr.* Rhume de cerveau.—*Germ.* Schnupfen.

In this fluid leucocytes appear to be always present, though only in small numbers; and, according to Hüter, micrococci are also abundant.

Sometimes an attack of nasal catarrh passes off as suddenly as it began. In two or three hours the flow may cease entirely; or the patient having been tormented with a "running cold" up to the very moment of going to bed, may forthwith fall asleep, and on waking in the morning may find himself entirely free. According to Trousseau, such a transitory coryza is sometimes an irregular manifestation of asthma, either leading directly to a genuine attack of that disease, or at least occurring in individuals subject to it. In cases of this kind there is little or no constitutional disturbance.

The more common kinds of nasal catarrh often set in with marked malaise and chilliness, and in children they may be attended with considerable pyrexia. The usual duration of such an affection is from two days to a week, but sometimes it lasts longer, or (it would perhaps be more correct to say) a series of attacks occur in succession, a fresh one setting in each time as the other is passing off. Whenever coryza runs on for more than a day or two, the discharge from the nose alters in character, becoming thick, opaque, and muco-purulent. Sometimes, as the nasal affection subsides, the larynx and the trachea are in their turn attacked with a like catarrhal inflammation. Lastly, a severe cold is in certain cases followed by a long-continued impairment or loss of the sense of smell.

In regard to the *causes* of coryza, it is in the first place to be noted that some individuals are far more liable to it than others, and that it is also especially apt to occur in certain families. There are persons who are sure to take cold if they get their feet wet; but such an over-susceptibility to catarrh may often be controlled by cold sponging in the morning, or by the use of a shower-bath, and by keeping the bedroom supplied with fresh air during the night. Among the public it is almost universally believed that nasal catarrhs are contagious; they are supposed to be easily conveyed from one person to another by handkerchiefs, or by the act of kissing.* It is uncertain whether the great prevalence of coryza at certain seasons of the year is to be regarded as a real epidemic, or as a result of the wide-spread distribution of the common exciting causes of the affection. As a matter of common observation, feverish colds "run through the house," but this generally occurs at times when they are prevalent.

A special variety of nasal catarrh must be mentioned which arises in certain individuals when they are taking iodide of potassium medicinally; this is supposed by Fränkel to be due to direct irritation of the lining of the nose by iodide dissolved in the mucous secretion.

It must not be forgotten that coryza is a prominent early symptom of measles, and sometimes of typhus.

An inflammation of the nasal mucous membrane that may be mistaken for an ordinary catarrh is sometimes dependent upon an infection of th nose with leucorrhœal or gonorrhœal discharge. In such cases, however, the exudation is from the first yellow and purulent, or mixed with blood, and the duration of the affection is much more protracted, lasting several weeks. Dr Hermann Weber, in vol. xliii of the 'Med.-Chir. Transactions,' seems to have first drawn attention to the possibility of the nasal cavities of an infant becoming infected during birth when the mother has leucorrhœa. Fränkel thinks that such an occurrence is by no means infrequent. In the

* Friedreich is said to have inoculated his nasal mucous membrane with discharges from persons suffering from coryza without any result.

'Lancet' for 1857 Mr A. M. Edwards relates a case of nasal gonorrhœa in a woman, who was ultimately shown to have caught it by using a handkerchief that had been employed as a suspensory bandage by her son.

Treatment.—Coryza is not a disease about the treatment of which one is often consulted, for most people manage their attacks themselves. It is well to keep indoors, and better to keep in bed, but few patients can do either. At the commencement ten grains of Dover's powder may be taken at bedtime with a basin of hot gruel, and next morning five grains of quinine. A warm bath is also useful; free perspiration seems to favour subsidence of the affection. Locally, marked relief often follows the insufflation of bismuth mixed with a little morphia, as advised by Dr Ferrier ('Lancet,' 1876, vol. i, p. 523). The late Dr. Williams recommended abstinence from all liquids. If there is no fever and the patient is allowed lozenges or orange-peel to suck, or a few teaspoonfuls of tea at intervals, the restriction is tolerable and prevents the profuse coryza. It applies best to those who are obliged to go about their work.

When nasal catarrh, instead of subsiding, persists for weeks together, change of air is often the best remedy; but the internal administration of arsenic is sometimes very useful under such circumstances, and striking results have been obtained from the same medicine when loss of taste and smell as the result of coryza had continued for many months; sometimes, however, it entirely fails.

Feverish colds.—Sporadic influenza.—The usually trivial disorder just described has considerable pathological interest. It is generally assumed to be the result of a chill, and few who are subject to it but can recall instances in which it follows directly and unmistakably as the result of exposure to a cold wind, or to rain, or to a draught of air. The first effect is a sudden feeling of chilliness, an involuntary shudder (*i. e.* a slight rigor), and a fit of sneezing. The reflex character of this spasmodic neurosis is shown by its being caused by a bright light irritating the eyes, as well as by cold air in the face or snuff in the nostrils, and also by its being prevented (inhibited) by pressure on the upper lip or bridge of the nose, and completely stopped by covering the face.*

But the same question arises which met us in the case of pneumonia. What seems a local inflammation determined by a chill to the surface, like bronchitis or pleurisy, assumes from another point of view the aspect of a specific fever, like measles. It sometimes comes on with no unusual exposure to cold; it "runs through the house" like a contagious disease; it is accompanied by malaise and pyrexia; it lasts for a limited time, and then subsides.

In one point it differs from other specific fevers, in that it does not protect against itself; or rather, perhaps, it protects for only a short time, for while relapses from an ordinary cold in the head are very frequent, a severe feverish cold rarely occurs except at considerable intervals.

The connecting link between the ordinary local coryza, described in the previous section, and the epidemic influenza, to be next considered, is furnished by what is somewhat loosely named a "feverish cold."

This, like the less severe and more local form, is usually the result of exposure to cold—particularly to an east wind blowing on the face; but it

* The action of the domestic remedy of smearing the nose with tallow or cold cream is to prevent sneezing by protecting the skin from cold.

is sometimes undoubtedly caught from another case of the same kind, and sometimes it is idiopathic, *i. e.* of unknown origin.

The symptoms begin with shivering or rigor, then there is usually pain in the throat felt on swallowing, together with headache and severe aching pains in the loins, the thighs, or the back and limbs generally. To this stage succeeds coryza and a short, dry, painful cough. The temperature rises, sometimes to 103° in an adult and often to 102°, the urine becomes febrile, the pulse quick, and the skin dry. After a day of distress, the skin begins to act, and the symptoms are somewhat relieved, but the coryza becomes more severe, a little mucus is expectorated, the bowels are constipated, and headache and pains in the limbs continue. After three, or at the latest four days, the feverish stage is almost always over, but there remains great prostration of strength for so short an illness, and considerable bronchial as well as nasal catarrh. Finally, there remains some cough and expectoration for a week or ten days more. Occasionally a sharp attack of diarrhœa seems to take the place of the nasal catarrh.

The *treatment* is first to avoid fresh chills, and secondly to keep warm. A hot bath or a Turkish bath is excellent, and for the time the patient feels well, but they do not cure; within an hour he is as ill as ever. He must go to bed, drink warm diluents, and get the skin to act. Dover's powder is certainly useful with most people. Some find antimonial wine more effectual in producing perspiration and relieving the pains and oppression. Low diet, salines, and laxatives are indicated, with constant warmth to the feet, the face, and the hands. Thus the patient gets comfortably through his malady. During convalescence quinine is the best tonic.

As prophylactics, covering the face and hands, or wearing cotton wool in the ears and nostrils, are the most effectual.

INFLUENZA.*—There is yet another form of catarrh of the nose, throat, and air-passages which is an epidemic, and probably a specific disease. This is the *influenza*, a name of Italian origin which came into use in 1741, and denoted its external origin and wide-spread sway. Its history is supposed to date from remote antiquity; but, as might be expected, doubts exist as to the real nature of many of the older epidemics.

There was an epidemic catarrh recorded in 1173, four similar epidemics in the fourteenth, and four more in the fifteenth century. According to Dr Parkes (in his article in 'Reynolds' System'), there were eleven in the sixteenth century, sixteen in the seventeenth, and eighteen in the eighteenth. Between 1800 and 1850 there were ten, of which three were the most important: one, in its spread over different countries, occupied the years 1830 to 1833; another occurred in 1837, when "half London" was attacked; and the third in 1847–8. This last was a very severe form. Many died from pleurisy, bronchitis, pneumonia, or pericarditis. At one time it was said that the whole staff of Guy's Hospital was laid up. It seems to be doubtful whether there was any reappearance of the disease, at least as an epidemic, during the second half of this century until the year 1889.

After having died out of the memory of the present generation, a severe and wide-spread epidemic of influenza has spread over the whole of Europe

* *Synonyms.*—Tussis epidemica (Sydenham)—Catarrhus a contagio (Cullen)—Catarrhus epidemicus—"the Chinese catarrhal fever"—"the Russian influenza."—*Fr.* La grippe.—*Germ.* Grippe.—*Ital.* Influenza. The word *grippe* is said to be derived from the Polish *crypka* or *grypka* (=*raucedo*).

and some other parts of the world while this edition is passing through the press, and is only now subsiding after several months.

The newspapers of November 26th, 1889, announced "a curious epidemic raging in St Petersburg; some authorities identify it with the dengue fever prevalent in Greece and Turkey (p. 346). The Russian doctors call it 'influenza,' the symptoms being fever and headache, accompanied by a running cold." Regiments were incapacitated and railways interrupted by the suddenness and severity of the outbreak. The disease spread quickly through Poland to Hungary and Vienna, where there was a considerable mortality. At the k. k. allg. Krankenhaus between December 7th and 14th, 165 patients, 57 nurses and 77 physicians were attacked. Other parts of Germany were visited, though less severely, as well as Italy, Spain, and France; afterwards the United States, Australia, and New Zealand. At the end of the year several cases had been reported at and near Chiswick, but the malady was slow in establishing itself, and some of the earlier cases reported were probably not genuine. In January and February, 1890, it was frequent in London, and our hospital wards and out-patient rooms were crowded with cases of catarrh and influenza. In the Foundling Hospital in January, 95 out of 315 children were attacked; and at the London Orphan Asylum 115 out of 500. At Hanwell, of 174 attendants 93 suffered, and of 1141 inmates of all ages 178. The disease after appearing in London visited the great provincial towns successively, and afterwards smaller places like Colchester and Cambridge, where at one college, St. John's, there were 70 cases. The severity of the epidemic was over in April, but scattered cases occurred until the end of May.

Course.—Most of the symptoms of influenza are those of a common feverish cold; but it is attended with greater pyrexia, and with more severe depression of strength. The patient perhaps suddenly becomes chilly and shivers, and for some hours he may feel exceedingly ill before any definite local affection appears. Early vomiting is not uncommon. When Sir Thomas Watson was first called to two cases on April 3rd, 1833, the symptoms were just those which mark the commencement of an attack of fever, and he did not then know what was about to happen; but by the close of the following day all London was smitten with the disease.

The pyrexia runs high, and there is intense pain "behind the eyes." The pulse is rapid, remarkably weak and small, and sometimes intermittent. After an interval the patient usually begins to sneeze, and a thin acrid fluid runs from his nose; his eyes grow red and watery, and his fauces are injected. In some cases, however, there is no coryza throughout. He becomes rapidly prostrate, so that he cannot keep up, and is obliged to take to his bed. He may suffer from giddiness or faintness; in some epidemics drowsiness is a common symptom, in others many patients become delirious. Pains in the limbs or cramps in the calves may be complained of. With the headache there is often a severe pain at the root of the nose, which is attributed to extension of the catarrh to the frontal sinuses. At the same time, or a little later, the patient is attacked with an irritating cough, dry, or attended with scanty expectoration of mucus without froth. Sometimes there is great dyspnœa, with a sensation of distress in the præcordial region, and frequent suffocative attacks. Loss of appetite is a marked symptom; the tongue is thickly furred; there may be nausea or vomiting; sometimes diarrhœa is present; the skin may have an icteric tinge. The urine is scanty and high-

coloured. In pregnant women abortion may occur, as the result (it is said) of the violent cough; or, if the menstrual functions have been suppressed from other causes, they are sometimes re-established. Facial herpes is sometimes observed.

At the end of from three to five days the attack passes off. If it lasts much longer either pneumonia has developed itself, or the catarrh of the air-passages has passed into ordinary bronchitis. The subsidence is sometimes gradual, sometimes by a critical sweating or diarrhœa; sometimes it seems to set in with epistaxis. The patient's convalescence is always slow, and he is long in regaining his strength. The subsequent prostration is remarkably severe and long continued. Relapses are not infrequent; few persons suffer more than one attack in the same epidemic. On the other hand, to have had influenza appears to confer no immunity against its recurrence on a subsequent occasion.

In some cases the disease assumes a rudimentary form, and the patient merely complains of slight coryza accompanied with sore throat and cough, and attended by a little malaise, headache, and disinclination for work—in fact, a feverish cold.

Sir George Baker, in his 'Opuscula Medica' (second edition, London, 1871), gives the following account of the epidemic of influenza in the year 1762. It was characterised by alternate heats and chills, by a constant cough, sometimes dry, occasionally accompanied by a little thin mucous expectoration. There was depression of strength, a sense of weight, and severe pain in the forehead and temples; inflamed, swollen, and watery eyes with photophobia; frequent sneezing and altered voice. There was painful rawness felt in the windpipe and chest, with, in some cases, a feeling of choking, and wandering pains in the arms, legs, and sides. The fever was chiefly nocturnal, but even then so slight that it rarely interfered either with sleep or with food. There was more or less perspiration, and when it was profuse the disorder was relieved or cured. The tongue was white and thickly furred; the urine was dark, and threw down a furfuraceous or lateritious deposit. In all cases there was more depression of spirits and loss of strength than the character of the disease seemed to account for, and convalescence was often tedious and imperfect. Many cases of abortion or premature birth were observed in London from this disease. In a few of the more severe cases there was a miliary eruption.

In the recent epidemic these symptoms were again observed. So far as the writer could judge from a limited number of cases, the attack usually began abruptly; the temperature rose higher on the first day than is common in any disease except scarlatina; the headache, lumbago, and pains in the limbs were unusually severe, and, with the not infrequent vomiting, resembled the onset of variola. The sore throat, coryza, and subsequent bronchitis were not different from those of a "severe cold." The bowels were usually confined, but sometimes there was sharp diarrhœa. A scarlatiniform rash was not infrequently observed. The urine was febrile, but very seldom contained albumen. The pulse was extremely rapid, and usually full and with rather high tension—rarely dicrotic. The course of the fever, as a rule, was not above three days, and sometimes less. The fall of temperature was very rapid, more so than in pneumonia. In one case, a strong, healthy young man was in full health on Saturday, had a temperature of 104·5° F. on Sunday, and by Tuesday afternoon was free from fever and from pain.

In some cases great prostration followed, and in many there was muscular weakness with malaise for several weeks after recovery.

Bronchitis was a frequent sequela, but the most important one was acute lobar pneumonia. In January, 1890, the writer saw in consultation with Dr Addison, of Colchester, a young man of twenty-seven ill with acute pneumonia of the left lung after influenza. He made a good recovery; but a brother three years younger had died a week before of the same disease, double lobar pneumonia after influenza; and a maid who had nursed him also died with acute double pneumonia. His mother, a younger brother, and a man-servant suffered at the same time from influenza, and the servant from pneumonia, but these three patients recovered.

Recovery from influenza has sometimes been followed by parotitis; often it appears to be the starting-point of phthisis.

Mortality.—It seems paradoxical to say that influenza is seldom fatal, and yet that it always causes a great increase of the death-rate; but the explanation is that almost all the mortality is brought about indirectly, and that the number of those who fall ill is greater, beyond all comparison, than in the case of any other epidemic disease. In London in 1847 not less than 5000 persons are said to have died of influenza in six weeks; but then it was computed that 250,000 persons were attacked. In Paris above one fourth of the population suffered; in Geneva not less than one third. Those who die are chiefly old and debilitated subjects, who have previously laboured under emphysema of the lungs, or who have feeble and dilated hearts. It is sometimes dangerous to very young children.* Parkes states that patients with lesions of the valves of the heart, and some at least of those who have phthisis, pass through influenza without being the worse for it; but other writers have remarked that after its subsidence phthisis often takes a very rapid course. Dr Farr pointed out, in 1847, that the mortality was much greater in those districts of England in which the death-rate was generally high than it was in healthier places. In February, 1762, the weekly death-rate at Warsaw ran from 30 or 40 to 150. In 1837 the mortality in 2347 cases was 2·3 per cent., in 1847 about 3 per cent. (Peacock). In 1889–90 it was probably lower than this throughout England, but in Vienna and for a time in Paris there was a higher death-rate, owing chiefly to subsequent pneumonia.

No special morbid changes are seen in the bodies of those who have died during an attack of influenza. The lungs and air-passages are congested, sometimes to an extreme degree, and there may be great œdema of the pulmonary tissue. Pneumonia is not infrequent, but this is regarded as a complication; it may be either catarrhal or fibrinous. Plastic exudation into the bronchial tubes has now and then been found.

Ætiology and pathology.—There have been many speculations as to the cause of influenza. No other disease diffuses itself so widely over the earth's surface. Not only is it capable of existing in all inhabited regions, so far as is known, but in some epidemics it has ranged over every quarter of the globe, and has established itself in places presenting all kinds of soil and every variety of climate. It therefore cannot be attributed

* But Sir George Baker writes of the epidemic in 1762, "*Leviter plectebantur infantes et liberabantur facillime.*" He found it most serious in advanced age, and particularly in asthmatic old men. The elder Dr Babington died of the influenza in 1833. Graves found the epidemic of 1837 very fatal among the aged, yet saw Judge Day recover at ninety-three.

to any "telluric emanation" or miasm; nor is it related to ague, for Holland, which is infected with malaria, has escaped some European epidemics.

Again, the progress of influenza from district to district occupies time. Many observers have thought that it commonly keeps to a definite direction, namely, from the east or north-east towards the west or south-west.

The epidemic of 1762 appeared at Warsaw in February, reached Vienna at the end of March, and Magdeburg in April; at which time it also invaded Hamburg and London. It was much more severe at Venice and at Warsaw than in England and Germany, and did not visit Paris at all. In June it was epidemic throughout Alsace,* and in July attacked the British fleet in the Mediterranean. After that month no cases were known to occur in Europe. Beside London, the towns of Manchester, Lincoln, Leicester, Exeter, and Norwich were seats of the disease, apparently by conveyance from the capital. Similar epidemics of catarrh or influenza had appeared at Norwich in 1733 and 1743. It was less common in country places—an argument in favour of its being infectious.

The epidemic which raged in London in 1833 is supposed by Hirsch to have been related to one which occurred in 1830 in China, and which reached Moscow later on in that year. In 1831 it spread over Russia, Poland, Germany, France, Sweden, Italy; it next appeared in the Isle of Man, and lastly in New Jersey, on the other side of the Atlantic. In 1832 it occurred chiefly in Spain and in some of the United States. In 1833 it broke out again in the north of Europe, and after extending over Russia and Germany, and passing to Denmark, it reached London in April. It was also observed at different dates of this year in Switzerland, the Tyrol, France, Italy, and Egypt.

The recent epidemic of 1889–90 was first observed in Russia and spread westward over the continent, attacking as usual the large towns earliest and most severely. It spread from Central Europe southwards over Italy and Spain, and northwards to England, where the smaller country towns were visited long after London, while many out-of-the-way places escaped altogether. In America and Australia the epidemic appeared later, and travelled over the United States in a westerly direction from the Atlantic seaboard to California.

It is particularly worthy of notice that both in England and France epidemic influenza seems only to occur as the result of extension from other countries. Some writers doubt whether it can arise in any part of Europe, and believe that it has its home in some remote part of Asia, perhaps Chinese Tartary. Hence the Russian name of the "Chinese catarrh," and the English name of the "Russian influenza."

Influenza often suddenly breaks out at the same time in places far distant from one another, and at once attacks a large proportion of their inhabitants; and it has been said to appear on exactly corresponding dates on board ships which had been long at sea, and which had sailed from ports where influenza was not prevailing. Thus in 1782, Admiral Kempenfeldt's squadron sailed from Spithead on May 2nd to cruise between Brest and the Lizard. On the 29th, there having been no communication with the shore, the men who formed the crew of one of the ships were attacked with influenza, and soon afterwards so many of the sailors on the other ships that by the second week in June the whole squadron had to

* These accounts were received by Sir Geo. Baker from Drs Jackwitz, Mertens, Kothen, Pringle, and Reimarus.

return to port. In the meantime another fleet, under Lord Howe, had sailed, all in perfect health, for the Dutch coast. Towards the end of the month of May the disease appeared in several of his vessels also, although there had been no intercourse with the land. So, again, on April 3rd, 1833, the day on which Sir Thomas Watson saw his first two cases of influenza in London, a vessel called the "Stag" was coming up the Channel and arrived at two o'clock off Berry Head on the Devonshire coast, all on board being well. The breeze was blowing from the land, and in half an hour forty men were down with influenza; by six o'clock the number was increased to sixty, and by two o'clock on the following day to 120. The very same evening a regiment at Portsmouth was in a perfectly healthy state, but by the next morning so many of the soldiers were affected by the disease that the garrison duty could not be performed. Parkes, indeed, expresses some doubts as to whether these instances can be entirely relied upon. But, as he says, if they are not altogether without foundation, they effectually disprove all chemical theories as to the cause of influenza; for neither a vapour nor any particles wafted in the air could travel such distances without undergoing dispersion and destruction. Nor is it possible that the materies morbi can be any substance, such as ozone, which, naturally present in the air in small quantities, might conceivably become enormously increased in amount over a wide area. For the disease, instead of affecting the whole of a town or city, sometimes confines itself to certain districts, or even to particular streets; and it may leave adjacent villages free.

Thus, by a process of exclusion, we are brought to the conviction that, unless the cause of influenza is something of the nature of which we have no conception, it must be a living thing, which is capable of reproducing and multiplying itself when once it has been introduced into a particular district or country. Nevertheless, though the discovery of the microbe of influenza was repeatedly announced in 1890, it is still unknown.

There have been numerous instances in which the complaint has first broken out in those particular houses of a town at which travellers had recently arrived from infected places; and there have also been examples of its having spared the inmates of prisons or convents, as though their isolation had served to protect them. But all that such cases can prove is that the contagion is capable of adhering to the human body, or to clothes or luggage, so as to be conveyed from one place to another. Cullen, indeed, defined influenza as *catarrhus a contagio*, but if he meant that it is contagious in the sense in which we now use that term, it is tolerably certain that such a view is incorrect. The disease seems to occur as frequently among persons who are confined indoors as among those who go about; it often attacks bedridden people; it does not spread from one patient to another, nor to relatives or nurses of the sick. It is decidedly more common in women than in men; children suffer less than adults, and in some epidemics they seem very generally to escape.*

* The absence of a stage of incubation is a remarkable exception from its general resemblance to the specific fevers. At the commencement of an epidemic of influenza an immense number of persons fall ill simultaneously or nearly so. If the disease took several days to hatch, one may be quite sure that the preliminary morbid process would not thus come to an end in every patient at the same time. Parkes, indeed, alludes to cases "in which the incubation period must have been two or three weeks," but on looking up the reference which he gives to Dr Robert Williams's work on morbid poisons, we find that the only instances given there are those already alluded to, in which the disease appeared on board ship when there had been no communication with the land.—C. H. F.

Epidemics of influenza have often been observed to last from four to six months, and their subsidence is scarcely less sudden than their commencement. In 1831 the disease prevailed in Paris for nine or ten months at a stretch. The recent epidemic lasted in England for about five months.

It is possible that the contagion may be derived from horses or other of the lower animals. Inoculation of horses with the blood of patients suffering under influenza was tried by Hertwig and failed. It is, however, not certain that the human disease is identical with the influenza to which horses are liable, and which, for example, raged in the United States in 1872, when it is said to have attacked about 16,000 horses in New York alone. During epidemics of human influenza, horses, dogs, cats, and even birds are said to suffer. But the disease in horses does not appear to spread to stablemen and grooms.

During the prevalence of an epidemic of influenza the only point to be mentioned in regard to its *diagnosis* is the risk of misinterpreting the early stages of other febrile complaints, such as enteric fever, rheumatism, or the exanthemata.

Sir Thomas Watson says that "in the years immediately succeeding an epidemic it generally shows itself again, but in a milder and less general form." And he goes on to say that "many of the colds and bronchial disorders of the seasons which follow a period of genuine influenza are attended with much more languor, debility, muscular aching, and distress than belong to an ordinary attack of catarrh." Parkes, however, states that sporadic cases are not met with; and we ought to protest against the practice of applying the term influenza to any severe catarrh, in order to add dignity to a common complaint.*

A further question remains as to the nature of certain localised forms of catarrh, affecting a greater or less part of the population of particular towns or districts. Thus in 1864 influenza is said to have existed in Switzerland, during the spring of 1867 in Paris, and so recently as 1874 in Cape Breton. As Parkes observes, strict proof that the disease in such "local epidemics" is really influenza ought to be required before they are admitted; but it is difficult to say how the proof is to be obtained.

With respect to *prognosis* we have already stated that an epidemic is only generally dangerous to infants and aged persons. But in anyone influenza is liable to end in ordinary acute lobar pneumonia, which as above stated is not infrequently fatal.

Treatment.—From an historical point of view it will always be interesting to know that bleeding and the administration of antimony were recognised by universal experience to be injurious in this disease at a time when they were regarded as almost essential to the cure of pneumonia and other inflammations. In the later epidemics quinine was found useful, even from the commencement of the attack; but the most usual practice was, after having given one purgative dose, to prescribe salines during the first day or two, and afterwards ammonia with senega or serpentary. Parkes insists that the custom of feeding the patient with hot beef-tea is a bad one; it invariably, he says, increases the headache and the languor. As there is complete loss of appetite, and as the attack may be expected to come to an end in a few days, it may be sufficient, if the patient is young and healthy, to let him

* Yet, as Niemeyer remarks, "diese Unsitte hat gewissermassen ihr Gutes. An einem Katarralfieber will Niemand erlieblich erkrankt sein und längere Zeit im Bette liegen; hat er aber die Grippe so ist er zufrieden wenn er nur in acht bis zehn Tagen genest."

have such beverages as iced-milk and soda-water, barley-water with lemon-juice, or weak white-wine whey. Except to elderly patients stimulants should not be given during the early stages. Afterwards, a good supply of food should be allowed, and at this stage tonics are often necessary. In the recent epidemic hot baths and diaphoretic drugs gave much relief, and antipyrin proved the most useful remedy for the severe headache.

OZÆNA.*—*Fœtid coryza.*—A very intractable and distressing form of chronic nasal catarrh is one in which the discharge from the nostrils, and even the air expired through the nose, has constantly a peculiar and disgusting fœtor.

With regard to many points about it there is still much uncertainty. Formerly it was thought to be generally dependent either upon "the scrofulous diathesis," or upon a syphilitic taint, congenital or acquired. There is, of course, no doubt that disease of bone in the interior of the nose, whether due to syphilis or to any other cause, may produce great fœtor. But the special odour that characterises ozæna exists without caries of the bones or ulceration of the mucous membrane.

All recent observers who have made autopsies in cases of ozæna appear to be agreed that in this affection there is an *atrophic* condition of the tissues within the nose, including even the turbinated bones. At one time it was supposed that this was the ultimate stage of a chronic "rhinitis," attended at an earlier period with thickening and swelling of the mucous and submucous structures. There is, however, no evidence of the occurrence of such an antecedent condition. Nor is it clear how the atrophy, when it has developed itself, is related to the fœtor. Some have thought that the current of air through the widened nasal passages is too slow to clear away the mucus by sneezing, and it therefore dries up and undergoes decomposition. Others hold that atrophy of the glands leads to an insufficient formation of mucus. In either case it appears probable that the process of desiccation is essential to the production of the offensive odour.

But there can be no doubt that mucus may and often does form dry crusts in the interior of the nose without any fœtor resulting. The explanation seems to be that for the production of ozæna a special ferment or microbe is required, the presence of which induces a particular kind of putrescence.

So penetrating is the smell in the worst cases of this distressing malady that it pervades the air for some distance round the patient, and renders him unfit for society. Yet he himself is often quite unconscious of it.

It must not be supposed, however, that the affection is always so severe as this. Fränkel remarks that about some persons, when they first wake in the morning, very faint indications of the ozæna-odour can be plainly recognised, which are altogether absent at other times. And, again, he says that in some cases in which mucus leaves the nose free from smell, it acquires more or less of the characteristic fœtor after drying on the handkerchief. This statement is confirmed by one's own observation. On the other hand, the contents of a spittoon or of a patient's spit-jar never smell like ozæna, perhaps because they are not allowed to dry up.

Treatment.—The usual method of treating ozæna has been by systematic

* *Synonyms.*—Chronic atrophic fœtid coryza—Rhinitis chronica (Fränkel)—Ὀζαινα (from ὄζω, I smell) was applied by Greek writers in the second century to a fœtid polypus in the nose. *Le punais, la punaisie,* are the vernacular names in French.

irrigation of the nose with water, or with saline solutions, or by injections of antiseptic agents, such as boracic acid or salicylate of soda. Of late a considerable advance seems to have been made by Gottstein, of Breslau, who simply introduces a plug of cotton wool into one nostril, leaving it there for twelve or twenty-four hours, and then withdrawing it, and plugging the other nostril in its turn for a like period. The effect is often successful so far as concerns the temporary removal of the fœtor. But almost as soon as the treatment is discontinued the case becomes as bad as ever. Ozæna is, in fact, at present incurable.

So serious is the discomfort entailed and so unsatisfactory have milder remedies proved, that more than once surgeons have undertaken the severe operation of extirpating the turbinated bones. (See on this subject a paper by Mr Warrington Haward in the 'Lancet' for 1877, vol. i, p. 784.)

EPISTAXIS.*—*Bleeding at the nose.*—Epistaxis occurs as a complication of many maladies. It is apt to accompany purpura and all hæmorrhagic diseases, and in splenic leuchæmia it is often an early symptom. It is more frequent in aortic than in mitral affections of the heart. Persons who have granular kidneys with hypertrophy of the heart are exceedingly liable to it, and in them it may often be taken as a warning of the probable supervention of uræmic seizures or of cerebral hæmorrhage. In old men it denotes vascular degeneration, and it is also frequent in cases of cirrhosis of the liver, with more or less jaundice and with dilatation of the small veins of the cheeks. "Bleeding at the nose," wrote the elder Heberden, "is a usual attendant upon the diseases of the liver in hard drinkers." It may accompany some of the acute infective diseases, especially variola and enteric fever. In cases of ague not only is it sometimes associated with the ordinary paroxysms of the disease, but it is said to have occurred periodically as the sole symptom and effect of malarial poisoning, until stopped by the administration of quinine.

But in the majority of cases bleeding at the nose is due to none of these causes. Boys towards the age of puberty are very subject to it spontaneously from time to time; and at any moment a slight blow upon the face, touching the nasal mucous membrane, or forcibly blowing the nose, may bring it on. In the 'Lancet' for 1865 Dr Guy Babington gave the history of a family in which marked liability to habitual and violent epistaxis was traced through five generations, and in thirteen out of twenty or more individuals. Some of those who suffer from recurrent or "habitual epistaxis are pallid, with apparently little blood to spare. But others are plethoric, with flushed cheeks and injected conjunctivæ; and they may experience from time to time sensations of oppression and giddiness, noises in the ears, throbbing in the head, fulness and heat in the nose, which they recognise as indications of the approach of an attack of hæmorrhage, and which are at once relieved when it occurs.

In some young women epistaxis has been observed to be distinctly vicarious of the catamenia. A striking instance of this is one recorded by Obermeier in vol. liv of 'Virchow's Archiv.' A girl of fifteen, after once menstruating in the ordinary way, began to suffer at regular intervals of a month from bleeding at the nose; this occurred two or three times a day for three successive days, and it was attended with malaise and other symptoms like those which had accompanied the natural flux. She became

* Ἐπίσταξις sc. αἵματος, a continual dropping of blood.

pregnant and the hæmorrhage then ceased, to return six weeks after her delivery. No doubt caution is required in accepting the statements of patients as to any form of vicarious menstruation; but this case appears to be beyond question.

In epistaxis the blood almost always comes from one side of the nose only; but sometimes part of it passes round behind the nasal septum and ultimately escapes from the opposite nostril, so that both sides may appear to be bleeding simultaneously. It may either flow in drops or in a more or less continuous stream; the quantity lost is in some cases very great. It is commonly of a bright red colour, this being perhaps due to exposure to the air after it has escaped from the vessels. It forms a solid coagulum. One can very seldom discover, whether by rhinoscopy or by inspection through the nostril, the exact point from which the oozing of blood takes place; nor have pathological anatomists as yet ascertained whether in cases of habitual epistaxis the veins in the submucous tissue of the nose (which are normally very wide and numerous) are in a varicose condition or affected with any degenerative change. It is, however, certain that not infrequently repeated epistaxis in adults is due to an ulcer of the septum, and in many cases to a perforating ulcer. This may depend on syphilis, but probably has more often a traumatic or accidental origin.

Sometimes part of the blood escapes through the posterior nares into the pharynx and is swallowed. Indeed, if the patient should happen to be asleep or recumbent from any cause, the whole of it may take this course; and when a large quantity of blood is subsequently ejected from the stomach by vomiting, the real seat of the hæmorrhage may be altogether overlooked unless a careful examination of the nose is made, when clots will be discovered in one or the other of the nostrils or in the pharynx.

The ordinary course of epistaxis is to cease spontaneously sooner or later. But it sometimes continues for many hours, or even for days, without intermission. In such cases the patient may rapidly pass into a condition of extreme anæmia, and may possibly die of syncope; and in other cases the frequent repetition of attacks of bleeding at the nose brings about a chronic state of bloodlessness that itself tends to favour the occurrence of further hæmorrhage. The process by which the natural arrest of epistaxis is effected appears to be by the formation of coagula, which adhere firmly to the mucous membrane and close up the vessels. Hence, after the cessation of an attack, any disturbance of the parts may at once cause a return of bleeding. Fränkel, in 'Ziemssen's Handbuch,' remarks that obstruction of the free part of the nose by clots, with apparent cessation of the epistaxis, affords no guarantee that oozing into the pharynx may not still continue, the patient swallowing the blood without knowing it; in the case of enteric fever, for example, great danger may arise in this way.

Epistaxis should not always be actively treated; as already observed, it may give relief to other symptoms of which the patient had been complaining, and it then generally ceases of its own accord. On the other hand, when anæmia is beginning to result, one must be careful not to delay too long in carrying out whatever measures may be requisite. Sometimes compression of the side of the nose against the septum by the finger placed just below the nasal bone is sufficient to arrest the flow of blood, at least for the time. It is important to notice whether this is the case; for, if so, one can be sure that the bleeding spot is in the forepart of the nasal cavity, and that one can stop all further hæmorrhage by the "anterior tam-

ponnade," that is by systematic plugging with a long strip of lint introduced through the nostril. But before adopting this method of treatment it is as well to make trial of astringents, such as gallic or tannic acid, which may be sniffed up in the form of a powder. To inject cold water or a solution of alum or any other astringent liquid is less advisable, because it tends to disturb any clots that may have formed. Cold may be applied to the outside of the nose, as well as to the whole of the patient's neck and chest. At the same time he may have his feet placed in a hot mustard bath. He should sit upright with his head slightly bent forward, so as to prevent the blood passing backwards towards the pharynx, and should keep the hands raised above the head. The most efficient internal medicine is ergot or subcutaneous injection of ergotin.

But if the hæmorrhage should continue, and if the source of it should appear to be from the back part of the nasal cavity, one must not wait long before having recourse to the radical method of the "posterior tamponnade," or "plugging the posterior nares." This is generally effected by means of an instrument which is described in every surgical work, and which is known as a "Belloc's cannula;" the plug being a piece of folded lint of suitable size and shape. It has, however, its disadvantages; for if the lint is not left undisturbed for some days, epistaxis is apt to begin again as soon as it is interfered with; while, on the other hand, if it be allowed to remain long *in situ*, there is often great difficulty in loosening it, and the mucous membrane may be torn. In any case it should certainly never be left to become fœtid by putrefaction of the blood and other fluids which soak into it. A better method is to fill up the nasal cavity with an elastic pouch, which, having been introduced in a collapsed state, is afterwards inflated with air until it exerts considerable pressure in every direction.

HAY-FEVER.*—Certain persons are liable every summer to a very troublesome affection, which sometimes assumes the characters of catarrh, sometimes those of asthma, and therefore may find its place provisionally between coryza, influenza, and spasmodic asthma. Attention was first directed to it by Dr Bostock in a paper read before the Royal Medical and Chirurgical Society in 1819.

Symptoms.—The *asthmatic* form will be considered separately (p. 1148). The *catarrhal* form sets in with a feeling of irritation in the nose, throat, and eyes. Then the patient begins to sneeze—perhaps twenty or thirty times in succession. A thin watery secretion pours from his nostrils. The nasal submucous tissue rapidly swells until in a little while no air can be drawn through the nose. If, however, he lies down and turns on his side, the nostril which is now uppermost becomes in a short time free (apparently as the result of gravitation of the œdematous fluid), while the other one becomes more occluded than before. The swelling affects the lachrymal passages also, so that the tears run down over the cheeks. The eyes become inflamed, and there may be œdema of the eyelids. So distressing are these symptoms that it is almost impossible for the patient to avoid giving way to them and suspending his usual occupations. From day to day they vary in severity, but they commonly last three or four weeks,

* *Synonyms.*—Hay-asthma—Periodic vaso-motor coryza—Specific or nervous coryza—Catarrhus æstivus—Catarrhus ex fœnisicio—Rose-cold and autumnal catarrh (U.S.A.).—*Fr.* Fièvre, asthme, ou catarrhe de foine, asthme d'été.—*Germ.* Heu-asthma, Heufieber, Bostock'sher Katarrh.

or even longer. Paroxysms of sneezing continue to recur from time to time. The nasal discharge presently becomes thicker and more purulent, or it may be stained with blood. Ultimately the affection passes off, leaving more or less weakness and prostration behind.

Exciting cause.—One of the first points observed about this "summer catarrh" was that its onset often corresponded closely with the beginning of the hay season, and that persons were attacked immediately after being in or close to a hayfield. But it was not until 1873 that Dr Blackley, of Manchester, discovered by careful observations and experiments upon himself that the true cause of the affection is the diffusion in the air of the pollen of certain plants, and especially of grasses, which settles upon the mucous membrane of the nose and eyes, and acts as a local irritant. Up to that time some medical writers had attributed hay-fever to coumarin,* others to ozone, others to "common dust," and others to the heat of early summer. Dr Blackley found that by introducing a small quantity of pollen into the nostrils he could bring on all the symptoms of the disease almost simultaneously. During the summers of 1866 and 1867 he made daily observations upon the amount of pollen which was deposited upon glass slides moistened with glycerine and exposed to the air; and he found that there was in general a close relation between the quantities collected and the severity of the symptoms of hay-fever under which he laboured from day to day. Dr Blackley appears to have accounted satisfactorily for certain observations which had seemed to Dr Bostock and others to prove that the supposed connection between summer catarrh and the emanations from flowering plants was a mistake. At any rate, he showed that when one might imagine that there can be no pollen in the air, it really may be present in abundance. Once he was suddenly seized while on the shore, with a sea breeze blowing; between him and the sea there was but a narrow belt of land, but upon this he found a field of wheat in full bloom. Another time an attack was brought on by the dust of an unfrequented country lane; it was summer-time, and on examining the superficial layer of dust with the microscope he discovered that it was full of the pollen grains of grasses.

Predisposing causes.—Hay-fever most commonly appears for the first time about the age of puberty, but sometimes it is observed in children four or five years old. Persons who have reached the age of forty without being affected with it are probably never attacked afterwards. It is more common in males than in females.

One very curious circumstance about this disease is that those who suffer from it appear always to belong to the educated classes. It is never seen among gardeners or farm labourers, who are of course more exposed to the influence of pollen than any other set of men. This fact has led to the suggestion that the individual predisposition to the disease, which plays so important a part in its ætiology, is perhaps a result of an indoors life, especially in towns or cities. Should that be the case, one can understand how it is that hay-fever appears to have become so much more common of late years than in the earlier part of the present century. In addition to the personal peculiarity, which we may call an idiosyncrasy or neurotic disposition or diathesis, Sir Andrew Clark believes that there is a local peculiarity in the nasal mucous membrane of those subject to this curious malady, which leads it readily to swell and become vascular.

* Or coumaric anhydride ($C_9H_6O_2$), an aromatic compound belonging to the Benzene group. It gives its scent to the grass *Anthoxanthum odoratum*, and to *Asperula odorata*.

It is supposed to prevail in England much more than on the Continent, but it is also very common in the United States, where it has been carefully investigated by Dr Mackenzie, of Baltimore. In most cases the susceptibility to the disease increases with each successive year. At first the patient may be attacked only when he is actually in a meadow where the grass is in full bloom; ultimately he suffers as soon as he attempts to go into the country during the hay season. Sometimes hay-fever assumes the asthmatic form after it has for several years recurred as a catarrh.

The treatment of hay-fever is extremely unsatisfactory. Neither quinine nor arsenic, nor any other medicine appears to have the power of enabling those who are liable to the disease to bear exposure to its exciting cause without being at once attacked by it. The local application of quinine in solution was first used in his own case by Professor Helmholtz, but it has not proved so successful with meaner sufferers. Sir Andrew Clark (after trying and discarding every kind of internal remedy, including aconite and belladonna) finds that a solution of cucaine (5-15 per cent.) applied locally with a brush, or as a spray or a bougie, is sometimes successful, though it often fails. As a more effectual plan, the same physician recommends the thorough local application of a solution of carbolic acid to the interior of the nostril (see the formula and method described in the 'Brit. Med. Journ.,' June 11th, 1887, p. 1256).

The most thoroughgoing treatment of all is to destroy the secretive parts of the Schneiderian membrane by caustics or galvano-cautery. This severe treatment has been carried out in the United States, and it is said with complete and permanent success.

For those who suffer severely, the only course (apart from local treatment) is to remain in a large town through the whole of the summer months, or else to go to the sea-side, choosing some narrow peninsula or island, or to take a sea voyage. Staying indoors during the middle of the day, even in a country house, often mitigates the symptoms.

The continuance of hay-fever during several weeks—generally from some time in May until the middle of July—depends upon the continued exposure of the patient to the irritant. If he can get away to a place where there is no pollen in the air, the attack quickly passes off.

When the symptoms begin considerable relief is afforded by the use of a smelling-bottle containing ammonia, iodine, and carbolic acid, made into a paste with wood-charcoal and compound tincture of benzoin.

WHOOPING-COUGH.*—Like so many other epidemic diseases, whooping-cough can be traced to only a comparatively recent period—the earliest notice of it is said to have been by Schenck in the year 1600. It is a very frequent and wide-spread disease, and, next to scarlatina, more fatal than any other in childhood; indeed, for infants under one year it is probably the most fatal of all.

Clinical course.—The *incubation* of whooping-cough after infection is perhaps variable—probably a fortnight as a rule, but often less.

* *Synonyms.*—Tussis clangosa (Glisson)—Pertussis infantum (Sydenham, 'Proc. Integr.,' cap. xliv, 1695)—Tussis puerorum convulsiva (Sydenham, 'Obs. Med.,' iv, 5, § 8, 1685; also Heberden and Cullen).—*Fr.* Coqueluche, Toux-qui-houpe (whence "hooping" cough, rationalised into "whooping").—*Germ.* Keuchhusten.—*Vernacular.* Chin-cough, a corruption of Chink-cough.—*Scottice.* Kink-cough, or Kink-host (Dutch Kinkhoest).—Kink or Chink means a catch in the breath (Skeat).

The *prodromal stage*, as it is sometimes called, is characterised by an ordinary bronchial catarrh, with a more or less troublesome cough and some pyrexia. Sometimes there is also nasal catarrh, with running at the nose and sneezing. The child (for whooping-cough chiefly affects children) is pale, out of sorts, and restless. According to Trousseau, the cough is sometimes remarkably frequent, recurring fifteen, twenty, or thirty times in the minute; in such cases there is generally high fever. He speaks of having been able to diagnose the disease at this period by the incessant repetition of the cough. But, as a rule, there are at this stage no symptoms by which its nature can be suspected, unless other cases have recently occurred in the same family or neighbourhood.

The duration of the prodromal stage is very uncertain. Sometimes in young children it lasts only a day or two, or it may perhaps be entirely absent. Sometimes it runs on for two, four, or even five weeks. In some cases it is believed to constitute the whole of the disease, the patient recovering without more distinctive symptoms; this was suggested by Cullen, and it has been recently supported by Dr R. J. Lee and Dr Eustace Smith.

In all but these somewhat doubtful exceptions a *developed stage* succeeds, characterised by the appearance of the "whoop" with the cough. The change in question may occur either suddenly or very gradually, so that the boundary-line between the two stages is often not to be fixed with any certainty. The cough may on some one or two occasions be attended with a sound which raises the suspicion of an experienced nurse or visitor, but several days may pass without confirmation of their suspicion. On the other hand, some healthy children, especially if they happen to cough while crying, make a crowing inspiratory noise that is not very different from the true whoop.

But when whooping-cough is well marked, there can be no mistake about it. Pyrexia is now absent, but the pulse continues very frequent. There may be a good appetite, and except for the cough the child may appear to be well. The cough comes on in paroxysms, of which there may be only a few in the twenty-four hours, or as many as sixty or eighty. They are usually more frequent in the night than during the day. Each begins with a series of short explosions in rapid succession, and these expiratory efforts have no noticeable inspiratory movements between them; then, after the air in the lungs has been reduced to the utmost, there comes a long-drawn inspiration, attended with a loud whooping or crowing sound that gives the name to the disease. The short explosive coughs follow, and then the whoop. Such a succession of attacks may continue for several minutes, and generally end by expectoration of a viscid mucoid fluid, or sometimes by ejection of the contents of the stomach.

It may well be imagined that the paroxysms of whooping-cough, when severe, cause great distress. The child, when it feels one coming on, runs to its nurse for support, or it clings to a chair or table so as to diminish the shock as much as possible. Patients old enough to take notice describe a tickling sensation in the larynx, or a feeling of compression about the throat, as though the air could not pass. Those who are younger betray the approach of an attack by restlessness and anxiety of face.

As the paroxysms continue, the child may become intensely cyanotic. The eyes protrude, the face and the neck become swollen, and a cold sweat breaks out. *Hæmorrhages* are by no means infrequent; the expectoration may be stained bright red by blood (which probably comes from the fauces or from the larynx), the nose may bleed, one or both of the conjunctivæ may

become ecchymosed, the tears even may be mixed with blood, or the tympanic membrane may be ruptured, with the escape of blood from the ear on one side or on both. Steffen (in 'Ziemssen's Handbuch') says that albumen sometimes appears in the urine. He adds that a momentary stoppage of the heart is not uncommon, and cites a case, in a girl six years old, in which there was a temporary loss of sight during each attack. He also speaks of a boy nine years of age, in whom, when severe paroxysms occurred, internal strabismus of the right eye was noticed, whereas the left looked straight forward, being held fixed with tonic spasm. Sometimes spasmodic movements of the muscles of the face occur. General *convulsions* are not of very infrequent occurrence, and they may prove fatal.

After the subsidence of the paroxysm, the child may be out of breath for a time and glad to lie down; sometimes he complains of headache, and sometimes is dull or fretful. But in many cases he begins to play again at once, and seems as gay and lively as though nothing had happened. When there has been vomiting, he often asks for food and eats it greedily.

Sequelæ.—Among the more remote effects of the violence of the cough is the formation of one or more shallow whitish ulcers on the under surface of the tongue by the side of the frænum; they appear to be caused by the lower teeth, against which the tongue is forced outwards during the paroxysm. In this country Dr Thomas Morton first drew attention to these ulcers in a paper read before the Harveian Society in 1876; but on the Continent they had been previously described by Bouchard and others. Dr Morton detected them in about 40 per cent. of his cases, generally between the third and the fifth week. He once saw an ulcer in an infant who had no teeth, when the tongue may possibly have been injured by the edge of the gums. The recognition of these sublingual ulcers may sometimes be useful in diagnosis.

Bronchitis and broncho-pneumonia are the most frequent and most important sequelæ. They are usually combined with lobular collapse.

Another result of whooping-cough is the production of pulmonary emphysema, and even the extravasation of air into the interlobular and subpleural areolar tissue, whence in some rare cases it reaches the mediastinum, and may ultimately diffuse itself under the skin of the chest, throat, and limbs. Or a pulmonary alveolus may rupture, so that pneumothorax results. Either of these affections may cause a fatal result.

Ascending paralysis has been once or twice observed after whooping-cough, probably due to peripheral neuritis.*

Prognosis.—It very seldom happens that a paroxysm of whooping-cough directly destroys life. A very young child, however, may die as the result of a complete closure of the glottis, or perhaps from syncope, or from the rupture of an intra-cranial blood-vessel. When the attacks are very violent and follow one another with extreme frequency, they sometimes give rise to a condition of apathy and stupor which is attributed to the effusion of serum upon the brain and its membranes, and this may terminate in death.

Much more often fatal are the pulmonary complications of the disease, bronchitis and broncho-pneumonia; it is said that they kill half or two thirds of all the children attacked. As may easily be supposed, patients who before were weakly and delicate are more likely to succumb to whooping-cough than the strong and healthy. It is far more dangerous

* Dr Samuel West has recorded a case of right hemiplegia with aphasia and athetosis, probably due to cerebral hæmorrhage during a paroxysm of whooping-cough ('Brit. Med. Journ.,' Jan. 22nd, 1887).

among the poor than among the rich. There are, however, differences of severity in different epidemics. It is more serious in its results during the cold seasons of the year than in the summer. When it affects adult patients it is very distressing, but it is not dangerous, nor is its duration generally prolonged.

The tendency of whooping-cough is, after a variable period, to subside. The expectoration which ends the paroxysms becomes looser, more abundant, and more puriform. The violence of the cough lessens, and the characteristic whoop disappears. Perhaps the length of time during which it continues to be heard may be from six weeks to two or three months. In a case related by Trousseau its duration was only three days; the patient was a child three years old, an inmate of the Necker Hospital. After the paroxysms have ceased, symptoms of ordinary bronchial catarrh may remain for a time. The child may be a long while in regaining its appetite and strength, especially if the season happens to be winter, so that there is difficulty in getting it out of doors and into the fresh air. Sometimes, when the whoop has apparently passed off, a fresh attack of catarrh brings it back again for a few days in as marked a form as ever. Even after the lapse of a year it may be noticed that the cough arising out of a simple cold is attended with a somewhat similar sound.

In some cases, even when the paroxysmal stage of whooping-cough has completely passed off, the child nevertheless fails to recover its strength, and ultimately dies of marasmus. Not infrequently pulmonary phthisis, with caseous bronchial glands, develops itself as a sequela. Permanent deafness and otorrhœa are said to be occasional results of the injury sustained by the tympanic membrane during the paroxysms.

Pathology.—There is still considerable uncertainty with regard to the nature of whooping-cough. That its proper place is among the infective diseases is suggested not only by its marked contagiousness, but also by the fact that those persons who have once had it are protected against future attacks. Indeed, Steffen says that its occurrence for the second time in the same individual, although not absolutely impossible, is far more rare than that of scarlet fever, smallpox, or any other exanthem.

It is said to be one peculiarity of the contagion of whooping-cough that it is far less apt than most other contagia to be transmitted to a distance in an active state. At the Evelina Hospital for Children the whooping-cough ward is separated by a short passage only from other wards on the same floor, whereas the wards for cases of measles and scarlet fever are isolated in a different building. We very rarely find the contagion of whooping-cough conveyed by persons not themselves affected with the disease. However, one can hardly doubt that it might be spread by the use of handkerchiefs or towels contaminated by dried secretions from the air-passages of patients; and a case is recorded in which linen sent to be washed on some island from a ship, on board which there were children affected with whooping-cough, conveyed it to the inhabitants of the island. In vol. xi of the Clinical Society's 'Transactions' there is recorded an observation, made by Dr Bristowe, of a case in which a lady appeared clearly to have conveyed the contagion of the disease from Sydenham to London upon her dress. During a visit to the former place a boy affected with whooping-cough, was climbing upon her knee and coughing and sneezing over her; she returned home the same evening, and early next morning one of her children was found playing over her dress, which had

been laid upon an ottoman. This girl took the disease, and afterwards gave it to two other children. A further point of interest is that the boy himself had only begun to have a constant troublesome cough on the very day on which the lady visited him; in fact, he was staying away from home in the hope that he might escape the disease, which was prevailing among his brothers and sisters. The case is also important as tending to show that the period of incubation in whooping-cough is about a fortnight; for the girl fell ill exactly thirteen days after she was exposed to the contagion, and the two other children sickened after about the same interval.

Climate does not appear to have much influence upon the prevalence of the disease, except that perhaps cold and damp countries are more favourable to it. And Hirsch has shown that it is not more apt to be epidemic at one season of the year than another. There are doubtless great individual differences as regards susceptibility to the contagion.

Female children are decidedly more liable to be attacked than males. The age at which whooping-cough is most common is between the first year and the eighth. Of Dr Goodhart's 314 cases 62 were under a year old, 212 were between one and four, 65 between four and six, and 13 between six and ten. Barthez and Rilliet recorded the case of an infant whose mother had had the disease for three weeks before its birth, and in whom severe paroxysms occurred on the second day. Sir Thomas Watson relates in his lectures how the grandchild of his bedmaker at Cambridge whooped on the very day of birth, there having been another child affected with the disease in the same house for three weeks before. Dr Eustace Smith found more than a fourth of a series of cases occurred in children under one year old. On the other hand, whooping-cough is sometimes observed in adults up to forty or fifty, or even a still greater age.* Heberden met with one case in a woman aged seventy, and another in a man aged eighty.

An association is often traceable between epidemics of measles and those of whooping-cough, children falling ill with the latter disease soon after having passed through the former. Such cases are peculiarly apt to be accompanied with severe broncho-pneumonia, and to have a fatal termination, the exanthem having often already brought the lungs into a morbid condition. Sometimes, however, the relation between the two diseases is reversed, measles breaking out after whooping-cough has existed for some time. It is then sometimes noticed that the paroxysms become much less frequent and much less severe than before, and that they remain so as long as fever persists; but the same thing may happen in cases of whooping-cough when pyrexia appears from any cause.

As already remarked, whooping-cough differs in one very important feature from infective diseases in general, namely, in not being attended with pyrexia at the time when its more characteristic symptoms are manifested. There is, however, a parallel instance in hydrophobia, and it is not impossible that Pasteur's discovery of the actual presence of the virus of hydrophobia in the nervous centres, and of its multiplication there, may hereafter be found to supply the key to the pathology of whooping-cough. One can easily imagine that the poison of this disease, having originally entered the air-passages from without, and having set up a catarrh there, is during the prodromal stage conveyed to some part of the central nervous system, and there sets up the peculiar spasmodic cough.

* An eminent London physician suffered severely from an attack of whooping-cough when more than sixty-five years of age.

None of the theories propounded hitherto really throw light upon this disease. Some have regarded it as a pure neurosis; some have attributed it to pressure upon the vagus nerve by swollen tracheal or bronchial glands; some have maintained that it is a mere catarrh of the respiratory mucous membrane. Beare, on the ground that the paroxysms of whooping-cough resemble those that follow the entrance of a foreign body into the larynx, would have it that the fundamental lesion is an inflammation of the tract immediately above the vocal cords. Observers differ as to whether or not reddening of the laryngeal mucous membrane can be seen with the laryngoscope during life; according to Rossbach ('Berl. klin. Woch.,' 1880) no morbid change is discoverable, either in the larynx or in the upper part of the trachea; according to Meyer-Hüni ('Ztsch. f. klin. Med.,' 1880) there is marked reddening, and even slight swelling, of most parts of the larynx (but not of the cords), as well as of the trachea.

Recent observations render it probable that the contagious principle of whooping-cough is an organism analogous to those which produce so many other infective diseases, and that it has already been seen with the microscope. As far back as 1870 Letzerich described and figured in 'Virchow's Archiv' a fungus, consisting of thallus-filaments as well as of spores. This is found abundantly in the sputa of patients affected with whooping-cough, and he asserted that he had succeeded in cultivating it, and also in producing a like malady in rabbits by inoculating the trachea of these animals with the product of his cultivation experiments. In the 'Jahrbuch der Kinderheilkunde' for 1876 Tschamer supported Letzerich's views, and also maintained that an identical fungus, commonly found adhering to the surfaces of oranges or apples, is capable of giving rise to whooping-cough when inhaled into the human air-passages. Afterwards, however, Burger, in the 'Berliner klin. Wochenschrift' for 1883, cast doubt on the accuracy of Letzerich's observations, while at the same time he asserted that the sputum in whooping-cough always contains large quantities of bacteria, which appear as rods of oval form, sometimes constricted in the centre, which are generally scattered quite irregularly, but occasionally arranged in chains. They are said to be easily brought into view by staining with fuchsin or methyl violet.

Treatment.—We have no specific or effectual treatment of whooping-cough. Sydenham depended on venesection; Fothergill and Armstrong advocated nauseating doses of antimony, and many less probable modes of treatment, as arsenic and nitric acid, have been from time to time introduced, to be in turn forgotten.*

In bad weather the patient should be kept in a spacious room, warm and equable in its temperature; for exposure to cold has a marked tendency to bring on the paroxysms, although according to Hauke the presence of an excess of carbonic acid in the air has a like effect. But in fine weather it is right to allow a walk out of doors in the middle of the day. When the disease lingers in its course, nothing is so likely to bring it to an end as change of air, especially to the sea-side. The meals should be nourishing and frequent, and should be given directly after a paroxysm. Talking, crying, and excitement of every kind should as much as possible be avoided.

* Moreover some of them are not free from danger. In the same number of a medical journal which narrated successful treatment of whooping-cough by antipyrin and antifebrin, there appeared an account of a doctor in Germany who nearly killed his own child by repeated doses of antipyrin during whooping-cough.

As regards drugs, *belladonna*, hydrocyanic acid, chloral, bromide of potassium or ammonium, hemlock, appear each of them to diminish the frequency and the severity of the paroxysms in some cases, and even to shorten the duration of the disease. But not one of these medicines can be depended on even in most cases; and they often fail altogether. Dr Eustace Smith strongly recommends sulphate of zinc (gr. $\frac{1}{6}$) and solution of atropine (B. P.) $\mathfrak{m}$ss, gradually increased in amount and frequency. Alum was introduced by the late Dr Golding Bird as an astringent in the later stages of the disease, and has often proved useful. Quinine also is sometimes serviceable; and the supposition that it checks the growth of the specific microphytes has led to its administration by insufflation into the air-passages.

In fact, it has lately become a common practice to treat whooping-cough by inhalations. The earliest attempts of this kind consisted in placing patients in the purifying chambers of gas-works, where the air is laden with tarry products, as well as with sulphuretted hydrogen and ammonia. According to Roger ('Bull. de l'Acad.,' 1880) the evidence of the value of this treatment is very doubtful.

A more recent plan is to impregnate the air of the patient's chamber with turpentine, or with petroleum, or with carbolic acid. A solution of carbolic acid, for example, is diffused through the room by means of a spray apparatus, or by simply heating a vessel containing it. Children who are old enough may be made to inhale a weak carbolic spray for fifteen or twenty minutes two or three times a day. Thorner, in the 'Deutsches Archiv' for 1878, reports very favourably of this practice; for about a week there was little change, but at the end of that time the symptoms of the disease began rapidly to subside. Successful results by similar means are reported in this country. Inhalations of the vapour from a boiling 2 per cent. solution of salicylic acid have also been recommended. Dr Goodhart has found both carbolic and salicylic acids disappointing.

Marshall Hall's suggestion of protecting the infant at night from draughts by a mosquito curtain has been tried with success.

ASTHMA.*—Until the present century the word asthma was used to mean what we now call dyspnœa; hence the phrase "cardiac asthma" was often used, and even at the present day it is common to hear persons spoken of as "asthmatic" who are suffering from bronchitis and emphysema. Indeed, soon after the discovery of auscultation Rostan and some other French physicians were strongly disposed to deny the existence of any disease occurring in persons with healthy lungs which required the name of asthma. But that there is such a disease there can be no doubt; and now that spasmodic or true asthma has been separated from other affections with which it used to be confounded, its characters are found to be exceedingly definite and well marked.

Symptoms of an attack.—Asthma is a paroxysmal affection. It sets in generally with remarkable suddenness; most frequently in the middle of the night, between 2 and 4 a.m., but in some cases at other times, between 6 and 8 a.m., or in the afternoon. The forenoon is almost always the period in the day when the patient is freest from it. In the same case it commonly begins at about the same hour. When this is, as usual, between two and four in the morning, the patient, who may have gone to sleep in perfect health, wakes up with a sense of oppression of the chest which soon

* Ἄσθμα (ἀσθμαίνω), *panting*, is a Homeric as well as a Hippocratic word.

passes on to the most extreme distress of breathing. But sometimes the seizure is preceded by symptoms which previous experience enables him to recognise as premonitory; among them are a peculiar drowsiness, flatulence, a slight degree of sneezing, a troublesome itching under the chin, the passing of a quantity of pale limpid urine like that secreted in hysteria. The urgent dyspnœa of the developed attack compels him to sit up, and perhaps drives him to the window, which he throws wide open, in the hope of getting air more freely. Or he may be obliged to sit with his elbows planted upon a table, or to stand with his hands grasping the mantelpiece or some article of furniture above his head; such attitudes being adopted for the purpose of fixing the shoulders and so assisting the muscles of forced respiration in their action. His face, at first pallid, becomes livid or purple, his eyeballs start from their sockets, his hands and feet are cold, his skin is covered with a profuse sweat, and his expression indicates extreme anxiety. In fact, he may appear to be at the point of death. There is sometimes a preliminary sensation, paræsthesia of various kinds, which Romberg happily called an asthmatic aura.

Examination of the chest shows that the physical conditions are as follows:—The breathing is not accelerated but of normal frequency, or even slower than natural. Its rhythm is perverted, the inspiration being short, whereas the expiration is greatly prolonged. With the inspiration there may be slight wheezing, but nothing in comparison with that of expiration, which is audible all over the room. The shape of the chest is such as corresponds with a very deep inspiration; the upper ribs are raised to the fullest possible extent, and the diaphragm has descended towards the abdomen, so that the area of pulmonary resonance extends considerably lower than natural. During inspiration the sternomastoidei and the scaleni are brought into action, but there is scarcely any advance in the degree of expansion; during expiration there is but little recession, although the rigid abdominal muscles can be seen and felt to be doing their utmost to expel air from the lungs. Percussion shows much less than the natural amount of difference in the relation of the edges of the lungs to the heart and liver during inspiration and expiration. The percussion-note over the chest is over-resonant. On auscultation, the inspiratory vesicular murmur is found to be almost or quite inaudible; frequently sibilus is heard in its stead, or sonorous rhonchi. With expiration there is heard through the stethoscope the same loud wheezing sound which has been already mentioned as being audible at a distance.

So entirely occupied is the patient with the mere act of breathing that he can scarcely utter a word, or turn his head, or even stop to cough; but after a time a slight cough comes on, leading to the expectoration of a few greyish-white pellets of mucus. Not infrequently the mucus is stained with blood, and sometimes there is considerable hæmoptysis. Expectoration generally indicates that the symptoms are about to subside.

The duration of a paroxysm of asthma is very variable; usually it lasts from one to three hours, sometimes only a quarter of an hour, and occasionally with but slight remissions for a whole night or a day. As it passes off the patient falls asleep, and when he wakes in the morning his breathing may be quite easy. The temperature is not raised. The urine after a fit is, according to Ringer, deficient in both urea and salines. But sometimes the disease continues for several days in succession with scarcely any abatement, except that there is almost always some increase in its severity at night, and some lessening during the early part of the day. In

such cases the patient's condition causes extreme alarm, although a fatal termination scarcely ever occurs. In the following instance, however, the breathing actually ceased, and life was maintained only by artificial respiration. Several years ago, one of our students, a strong healthy young man, devoted to football, was admitted into the Clinical Ward labouring under a severe attack of asthma, to which he was subject. A few hours later, the house physician, who was sleeping in an adjoining room, was hastily summoned on account of an alarming failure of the patient's breathing. His respirations became more and more shallow, and at last they ceased altogether; he fell forwards in a state of insensibility, and remained unconscious for several minutes. Artificial respiration was resorted to at once, and with success. If medical aid had been less prompt there is little doubt that he would have died.

When asthma passes off in the usual way it is apt to return during the following night. The paroxysms may, in fact, recur for several successive nights, and may then cease, leaving the patient entirely free for weeks or months together; but there are other cases in which the disease shows itself night after night for years. A friend of the author's, who was liable to asthma for the last twenty-five or thirty years of his life, was never able to lie down to sleep; when night came on he dressed himself in a flannel suit, and seated himself in a large chair, where he remained till morning.

Diagnosis.—From the above description of asthma it will be apparent that the disease ought never to be mistaken for those tracheal or laryngeal affections (such as bilateral paralysis of the abductors of the cords) in which the dyspnœa is mainly inspiratory.

But it is often only by the history that one can tell whether a patient is suffering from asthma or from bronchitis and emphysema. According to Trousseau, a child (or even an adult) may be seized with what appears to be an acute and dangerous attack of broncho-pneumonia, with abundant moist sounds over the chest; and yet the subsidence of the symptoms in the course of a day or two, and the recurrence of like attacks on future occasions, ultimately show that the affection is really asthma.

The relations of bronchitis and emphysema to asthma are somewhat complicated. On the one hand, it is not uncommon for patients who have chronic bronchitis to suffer from time to time from paroxysms of dyspnœa, which cannot be accounted for by any increase of the bronchial inflammation, and which seem referable to a concomitant spasm of the air-tubes; if such spasm is regarded as the essential condition in asthma, it may be said that in these cases *secondary* asthma is present as a complication of the bronchitis. "Bronchitic asthma" was recognised by Salter; it is constantly worse in the winter than in the summer, which is not generally the case with primary asthma.

On the other hand, if a person with healthy thoracic viscera becomes subject to frequently recurring attacks of asthma, his lungs sooner or later become emphysematous. We have seen that during the paroxysm of asthma the ribs are raised, and the diaphragm at a lower level than natural; in other words, the lungs are in a state of over-distension. When the symptoms quickly pass off, as is usually the case, the chest walls return in a few hours to their normal position and the lungs to their normal size. But if similar attacks recur again and again at short intervals, the inevitable result is that the elasticity of the pulmonary tissue is impaired, and thus the alveoli become permanently over-stretched and emphysematous; ultimately the right side of the heart dilates, dropsy sets in, and there follow

the other mechanical results of general venous congestion, as in the last stage of chronic bronchitis.

Patients with confirmed asthma gradually acquire a characteristic aspect, which was well described by Salter. They are round-backed, high-shouldered, and stooping; the chest is obviously rigid and without pliancy, and from it the arms hang suspended, but inclined rather backwards and bent at the elbows. They are thin almost to emaciation, with prominent veins, cold thin hands, and a dusky complexion. The cheeks are hollow, the eyeballs turgid and watery, the mouth generally open, and the jaw rather hanging. The voice is feeble and somewhat hoarse and rough.

Ætiology.—With respect to the causes of asthma two questions have to be asked: (1) What are the *predisposing conditions* which render certain persons susceptible of the disease, whereas other persons seem to be incapable of being affected by it? (2) What are the various *exciting causes* which, in such individuals, are found to bring on the paroxysms?

The answer to the first of these questions must at present be incomplete, while of the *causa efficiens*, the invariable antecedent of asthma, either regarded as a paroxysm or as a diathesis, we are quite ignorant.

Inheritance has a share in the ætiology of asthma. Salter gives many striking instances of the transmission of asthma from generation to generation; and also mentions cases in which several brothers and sisters in a family were asthmatic without the parents being so. Walshe likewise gives instances of three or four brothers or sisters being asthmatic without the disease having appeared in the family before for at least the preceding generation. This kind of connection, which is not hereditary so much as consanguineous, we have already noticed in the case of certain undoubtedly nervous maladies, *e. g.* Thomsen's disease (p. 734). It is a point of great interest, and requires more investigation than it has yet received.

In early life many cases appear to be directly traceable either to *measles*, to *whooping-cough*, or less certainly to an attack of ordinary bronchitis; at the time the child seems to recover perfectly, but it becomes for the future liable to asthma. Other facts suggest that the disease is a *paroxysmal neurosis*. Thus Salter relates the case of an epileptic patient whose fits, after the usual premonitory symptoms, were on several occasions replaced by asthmatic paroxysms. This is, however, very exceptional; nor is it pretended that there is any connection between asthma and hysteria. Another of Salter's cases is that of a gentleman in whom a violent attack of asthma was twice suddenly excited by fear. Walshe also tells how an asthmatic patient, who had forgotten to take his cigarettes of stramonium and belladonna out with him, was so alarmed on discovering his omission that the dreaded attack at once came on.

Again, asthma is said to be sometimes closely related to gout. It has been observed to alternate with cutaneous eruptions, becoming worse when the skin has got better, and *vice versâ*. Sir Andrew Clark has particularly called attention to the frequent coexistence or alternation of asthma and *urticaria*, and has founded thereon the hypothesis that the immediate cause of a fit may be urticarial swelling of the bronchial mucous membrane, both the cutaneous and the mucous wheals being the result of sudden vaso-motor disturbance.*

The *age* at which patients first become affected with asthma is very variable. It sets in during childhood much more often than used to be

* See also a case in point related by Dr T. D. Pryce in the 'Lancet' for May, 1886.

supposed. Salter found that in a fourth of his cases it had begun before the tenth year, and he saw two cases in infants, one fourteen and the other twenty-eight days old. More *males* than females suffer from asthma, in the proportion of two to one.

The *exciting causes* of the asthmatic paroxysm vary widely in different cases. Indeed, hardly any two patients agree in their statements as to the precise conditions which bring on their attacks.

Particular kinds of weather, certain winds, cold air, the confined air of crowded rooms or railway carriages, act as exciting causes in some cases. Or the attack may follow the inhalation of dust, flue, or smoke, even the smoke of an extinguished candle or of a lucifer match.

Some patients are sure to be seized with asthma if they come near certain kinds of animals: cats, rabbits, dogs, horses, guinea-pigs, or the smaller Carnivora of a menagerie. Salter relates many remarkable cases of this kind, and what is especially noteworthy is that years have often passed before the patient discovered to what his sufferings were due. One man, a livery-stable keeper, was continually asthmatic until he retired from business, and then became almost entirely free; but whenever he went back among the horses the disease returned, and so at last he found out what was for him the special exciting cause. The writer once knew a lady who was attacked with asthma whenever she was in the same room with a cat; the animal could not be hidden anywhere near her without her discovering it by a painful sense of constriction in the air-passages.

The asthma produced by hay, or rather by the pollen of grasses, is one form of the disease known as hay-fever (p. 1134). Some patients never have asthma unless they are exposed to the influence of the pollen; others are habitually asthmatic, this being only one of many causes capable of exciting the disease in them. Many persons are attacked if they inhale the powder of ipecacuanha diffused in the air, and odours of various kinds act as exciting causes in particular cases.*

Diet plays an important part in setting up the paroxysms in almost all asthmatic patients. Heavy suppers and late dinners are very injurious; many asthmatic persons are unable to eat any solid food for several hours before bedtime. Special articles of food, among which are cheese, nuts, coffee, bottled stout, and wine, are apt to provoke the disease.

Another occasional cause of asthma is the presence of polypi in the nose. This was first pointed out by Voltolini; it has since been confirmed by Haenisch. Removal of the nasal growths frees the patient from the liability to the recurrence of the bronchial affection.

Salter mentions one case in which a paroxysm was sure to occur if the rectum was allowed to remain loaded. Sometimes, again, the attacks are clearly traceable to uterine irritation, as when they return with each catamenial period, or come on only during pregnancy or parturition.

But of all the exciting causes of asthma the most important in its influence is *locality*. And here, again, there are the strangest differences between different cases, so that it almost seems as if the disease were regulated by caprice. In certain places the patient is sure to be attacked; in others he is as sure to escape. As a rule, the places most favourable for asthmatic subjects are large, crowded, smoky towns, like London, Glasgow, and Manchester. The most extraordinary stories are related by Salter of the effects of London air. Persons whose lives had been rendered

* See the graphic narratives of such cases of asthma given by Watson and Trousseau.

miserable for years have become entirely free from asthma after moving to London. He thought that three fourths or seven eighths of all cases of asthma might be cured in this way. A patient of Dr Walshe found that he could only live in perfect freedom from his asthma in the Seven Dials. It is to be noted that the influence of locality extends to neutralising the ill effects of some other exciting causes of the paroxysms; the patient may be able while in London to eat what he pleases and at whatever hours, whereas in the country the strictest dieting may be required to keep off the disease. On the other hand, there are a few cases in which the air of the sea-side or of a bracing hilly district is found to be the best.

Pathology.—Various theories have been framed to account for the paroxysms of asthma, but even now the pathology of the disease cannot be said to be fully established. The *expiratory* character of the dyspnœa, exactly like that which accompanies capillary bronchitis, seems clearly to show that it must depend upon a morbid affection of the very small bronchial tubes within the lungs. During the act of expiration these tubes are as much exposed to pressure as the pulmonary alveoli themselves, and it is not difficult to suppose that, when from any cause they are partially obstructed, they may admit air into the lungs in inspiration, and yet refuse to allow it to pass out in expiration. The question is, What is the nature of the obstruction in asthma? The most obvious suggestion certainly is that it results from spasm of the muscular fibres in the walls of the tubes. That these fibres are capable of contracting, so as to narrow to some extent the calibre of the tubes, has been established by physiologists. The suddenness of the onset of the asthmatic paroxysm, the eqnally sudden way in which it sometimes subsides under the influence of a violent mental shock or emotion, the marked effect of such remedies as chloral, belladonna, and stramonium in bringing it to an end, the relation which appears to exist between asthma and certain neuroses, all favour the view that it is essentially spasmodic in nature. On the other hand, it is by no means clear that spasm can account for such considerable narrowing of the tubes as must be present in asthma; or that spasm can be kept up for so long a time as is sometimes occupied by a prolonged paroxysm of the disease.

Another hypothesis is that the mucous membrane of the tubes becomes very rapidly swollen by what German writers term a "fluxionary hyperæmia," or (as Weber put it) by "a dilatation of its blood-vessels through the influence of the vaso-motor nerves." The fact that the catarrhal form of hay-fever is attended with an obvious swelling of the mucous membrane of the nose is a strong point in favour of this view; since it seems unlikely for the asthmatic form of the same disease to be altogether different in pathology. Sir Andrew Clark's theory of the nature of this supposed swelling has been already referred to. Störk is said to have actually observed with the laryngeal mirror that during an asthmatic attack the whole length of the trachea and part of the right bronchus were deeply congested. It is possible that the small bronchial tubes may be affected both with hyperæmia and with spasm.

In 1871 Leyden discovered in the sputa certain pointed octohedral crystals, identical with those which are found in the blood and viscera in cases of leuchæmia, and commonly known as Charcot's crystals, having been first described by him. Leyden's idea was that these crystals might perhaps constitute the starting-point of the asthmatic paroxysm, by irritating the peripheral ends of the branches of the vagi in the bronchial

mucous membrane, and so setting up a reflex spasm of the muscular fibres beneath. But this is not at all probable, and they have been observed in the sputa of patients not suffering from asthma.

Prognosis.—When asthma occurs in childhood, it generally subsides about the age of puberty, leaving the patient free for the rest of his life. On the other hand, persons above the age of forty or forty-five seldom if ever get rid of a liability to it. The longer and the more frequent the paroxysms the more serious is the case. It is important to notice whether in the intervals between the attacks there is any shortness of breath, or cough with expectoration. For such symptoms indicate that the asthma is complicated with chronic bronchitis, or emphysema; and the presence of any permanent organic lesion of the lungs seriously adds to the gravity of the disease. The popular notion that "asthma is a lease of long life" is quite mistaken. It only points to the fact that death in the fits is extremely rare, and that so apparently severe a disease does not kill rapidly. All life insurance offices know that asthma leads in time to emphysema and its consequences, and reject or heavily "load" such cases.

Asthma does not tend to develop phthisis; although, on the other hand, there are cases which prove that it does not prevent its supervention.

Treatment.—This falls under two heads: we have, first, to prevent the recurrence of the asthma; and secondly, to relieve the attacks when they develop themselves, and, if possible, to cut them short.

In endeavouring to prevent the attacks, the most important thing is to study the exciting causes in the individual patient, and as far as possible to remove them. The digestive organs and the diet demand the first attention; then the place of residence. A drug which is in some cases very serviceable, although its mode of action is obscure, is the iodide of potassium; but it often utterly fails.

For the paroxysms of asthma different modes of treatment are useful, some in one case, some in another. Many patients are at once relieved when they are made faint and sick by an emetic dose of ipecacuanha or by smoking tobacco. The latter is said to be the best remedy for hay-asthma; unfortunately, those who smoke habitually get no benefit from it. In some cases nothing does so much good as strong hot coffee taken on an empty stomach, or hot whisky and water. In other cases the inhalation of chloroform gives very rapid, but generally only temporary relief. Smoking the leaves of stramonium (or of one of the other species of Datura) is often very effectual. Or the patient may try stramonium as a tincture or an extract, or the ethereal tincture of lobelia in full doses, or tincture of belladonna, or chloral. Some patients derive great benefit from the fumes of nitre-paper, burnt so as to fill the room with white smoke. In other cases nothing does so much good as the inhalation of a green powder which is sold as Himrod's cure for asthma in the United States, and is said to consist of nitre, stramonium, and aniseed. Chloroform and chloral hydrate are uncertain in their effects; and galvanism is probably useless.

For details in the management of cases of asthma the reader should consult the late Dr Hyde Salter's work, based as it is upon a large experience as well as upon his own sufferings from the disease. It contains on almost every page practical hints of the greatest value.
